Periodic Ground-based Monitoring

Biologists periodically checked the placement of each trial specimen to guard against misleading indicators of carcass removal, such as wind blowing the trial specimen out of the camera's field-of-view. To minimize the potential for scavenger bias caused by the activity pattern of biologists, every camera was checked (not just those with trial specimens) following a standard schedule. Whenever possible, ground-based monitoring took place during times of the day when potential scavengers were the most inactive (i.e. middle of the day). Often times, the placement and persistence of trial specimens was checked from a distance, using spotting scopes or binoculars, to avoid close approach. At least once every week, cameras were checked for proper functioning at the same time that ground-based monitoring occurred.

The following table provides a schedule which outlines the periodic ground-based monitoring of trial specimens:

Table 2. Carcass Removal Assessment – specimen placement and ground-based monitoring schedule.

Results

Round 1

Of the 30 carcasses placed during Round 1, 8 medium, 3 large, and 6 small trial specimens (56%) were completely removed during the 30-day trial period. The average time (number of days) a carcass persisted before removal (out of a maximum of 30) was 24.6 for large carcasses, 10.9 for medium carcasses, and 15.7 for small carcasses for an overall average of 17.1. Six of the 13 remaining carcasses (4 small and 2 large) were present and wholly intact at the conclusion of the trial, two large carcasses were present but scavenged, 4 were disarticulated (3 large and 1 medium) and 1 medium carcass remained detectable as a feather spot. Full monitoring results are present in the attached Excel Spreadsheet.

It took 19 days before 50% of all trial specimens were removed (Figure 4). The percentage of trial specimens removed remained constant at 50% between 19 and 27 days. The data indicates a spike in removal rates between 4 and 6 days following the placement of trial specimens. The removal rates then remain relatively constant. For the 17 carcasses that were wholly removed, 9 were detected during ground-based monitoring as having been scavenged, but still detectable while the other 8 were present and wholly intact until they were removed completely in one incident.

Round 2

Of the 30 carcasses placed in Round 2, 5 medium, 4 large, and 10 small trial specimens (63%) were completely removed during the first 32 days (Figure 4). These data were used for the graph to compare similar time periods, but rather than collecting carcasses after 30 days, as we did in Round 1, the carcasses in Round 2 that had not been removed were left in place to determine how long they would actually persist in this environment. Due to the need to start a new round, all remaining carcasses were eventually removed on 9 December 2014, 107-117 days after placement. The average time a carcass persisted before removal (maximum of 117) was 68.3 days for large carcasses, 44.6 days for medium carcasses, and 12.6 days for small carcasses for an overall average of 40.7 days. At the conclusion of the trial, 5 carcass remains (4 large and 1 medium) were still detectable. Full monitoring results are present in the attached Excel Spreadsheet.

It took 23 days before 50% of all trial specimens were removed (Figure 4). Unlike Round 1, a sharp spike in carcass removals was not detected at any point during the trial. Instead, a steady removal rate was observed over time. For the 19 carcasses that were wholly removed, 7 were detected during ground-based monitoring as having been scavenged, but still detectable while the other 12 were present and wholly intact until they were removed completely in one incident.

Round 3

In Round 3, 80% of the carcasses (10 small, 7 medium, and 7 large) were completely removed during the first 30 days. All carcasses were collected on 21 January 2015 which was 34-36 days after placement. At that time, 4 specimens still persisted as detectable feather spots. The average number of days carcasses persisted before removal (out of a maximum of 36) was 18.9 for large carcasses, 12.1 for medium carcasses, and 3.7 for small carcasses for an overall average of 11.6 days.

Over 50% of the carcasses were removed within 6 days of placement. As in Round 1, a very sharp spike in removal was observed during the first few days of the trial, although the spike was much sharper in Round 3 than in Round 1.

Round 4

At the time Round 4 was conducted, Corvus experienced some difficulty obtaining small carcasses for the trial; as such, West, Inc. provided data for 2 small carcasses which were placed on 4/27/2015 following completion of the Corvus Round 4 trial. Only 43% of the carcasses were removed during the first 30 days of the Round 4 trial. The original 28 carcasses were collected on 27 April 2015 (31-35 days after placement). At that time, 8 large and 5 medium carcasses were still detectable. Average carcass removal times (out of a maximum of 35 days) were 6.6 days for small, 20.9 days for medium, and 30.5 days for large. The overall average was 19.3 days.

In Round 4 it took 31 days before 50% of the placed carcasses were removed. The most striking difference between the fast removal of small specimens and the very slow removal of the large specimen was observed in Round 4.

All Rounds Combined

If data from all Rounds is pooled and the maximum number of days until removal is reset to 30 for all Rounds, the overall averages are 23.8 days for large carcasses, 15.4 days for medium, and 9.7 days for small (Table 3; Figure 5). The combined average is 16.3 days. A one-way ANOVA was run for each trial looking at size class as the source of variation (Table 3). The data showed that size was a significant factor in removal times in all but Round 1 at α = 0.05. The results of Tukey-Kramer multiple comparisons are summarized in the table. The same size class in different rounds was also compared to look at seasonal differences. The medium and large size classes showed no significant differences at α = 0.05 between rounds. The small size class was significant at α = 0.05 as was the combined average of all size classes. The Tukey-Kramer multiple comparisons revealed that the only significant differences were between the small size class removal times between rounds 1 and 3. A Two Factor ANOVA was run to examine the pooled results and found significant differences among the size classes and among the rounds, but the interaction between the two factors was not significant (Table 4). It is important to note that these numbers were scaled down to a maximum of 30 days when, in reality, it is likely that the large carcasses would persist for a much longer time.

Scavengers

There were three main scavengers present during all three trials: Common Ravens (*Corvus corax*), kit foxes (*Vulpes macrotis*), and Turkey Vultures (*Cathartes aura*). Kit Foxes were the most prevalent scavengers caught by the cameras (Table 4). During Round 3, kit foxes scavenged at 100% of the carcasses placed. Wind was the main factor in removal of feather spots.

Figure 4. Percentage of each size class removed over time for Round 1 through 4.

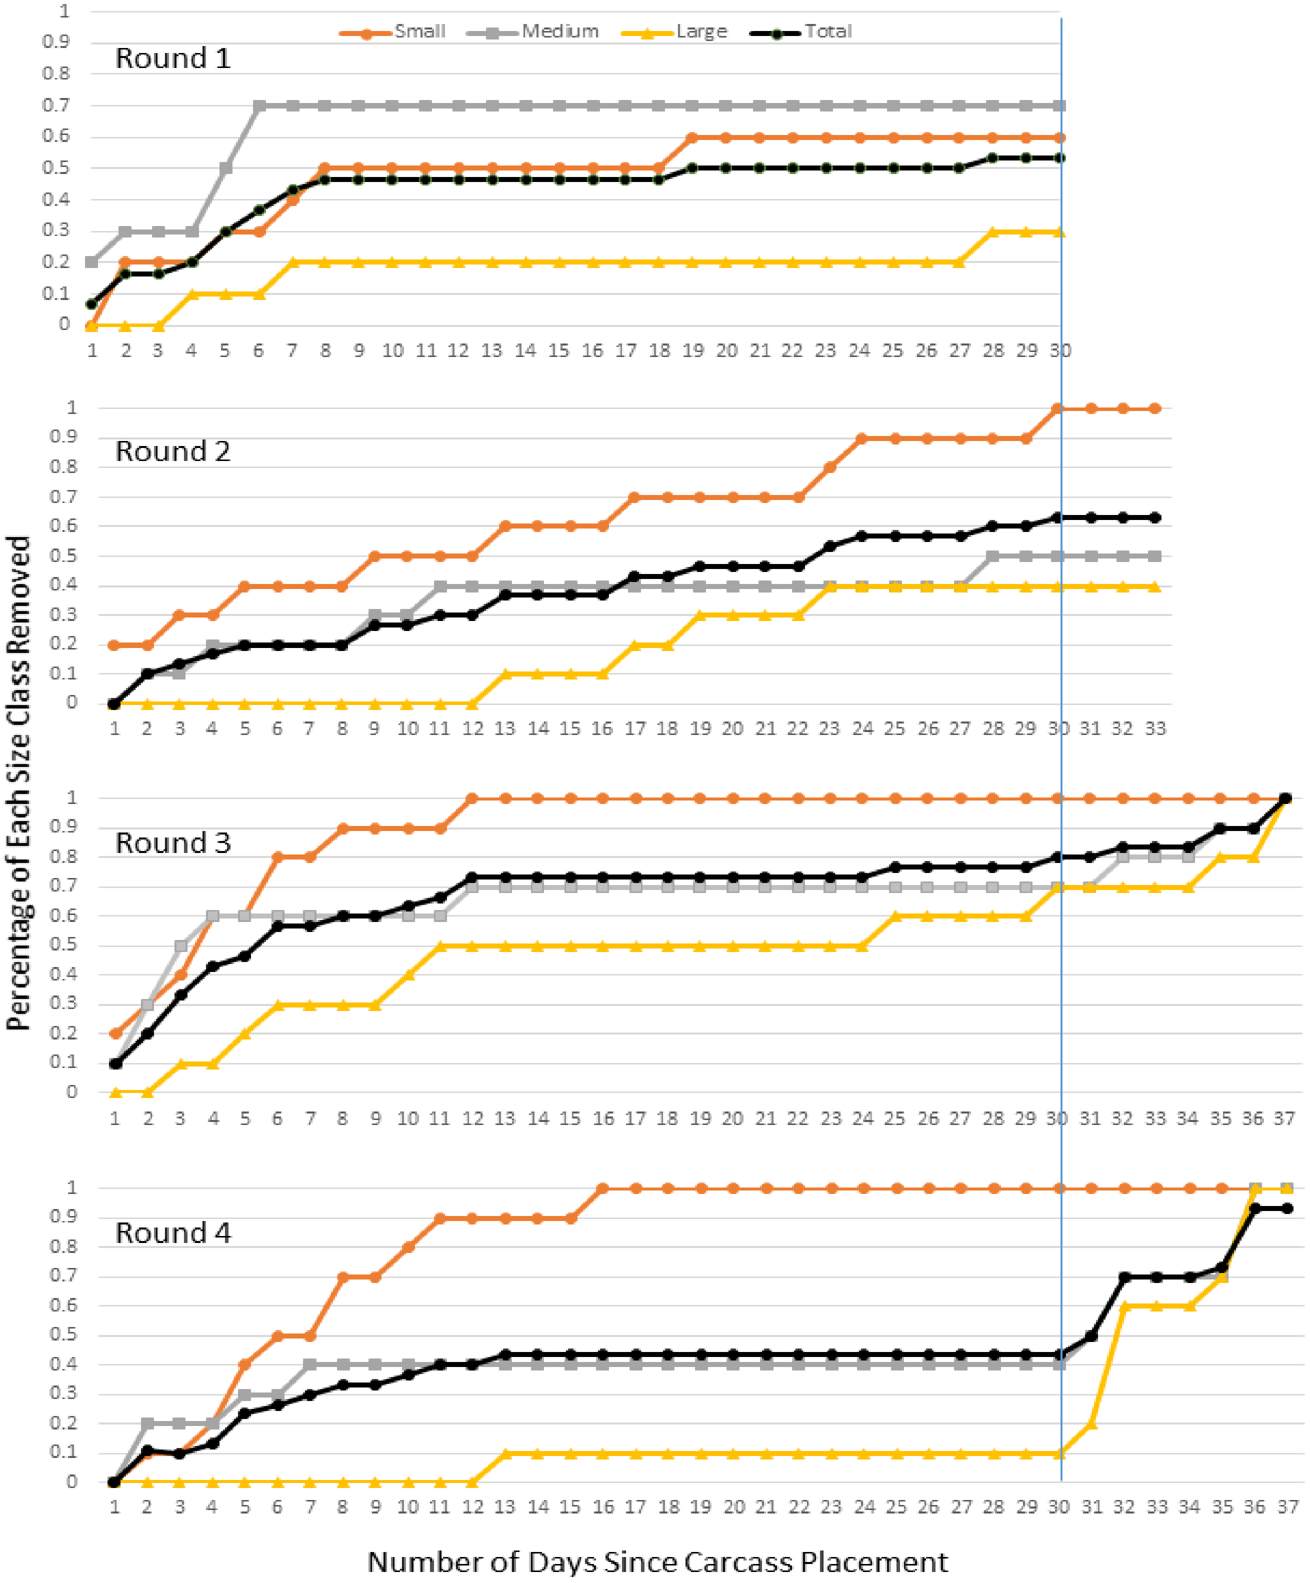

Table 3. Average # of days a carcass persisted in each trial (out of a maximum of 30) with the P-value associated with the ANOVA to test for significant differences between size classes.

Size	**Round 1**	**Round 2**	**Round 3**	**Round 4**	**Overall**	**P-value comparing rounds**

Spatial Analysis

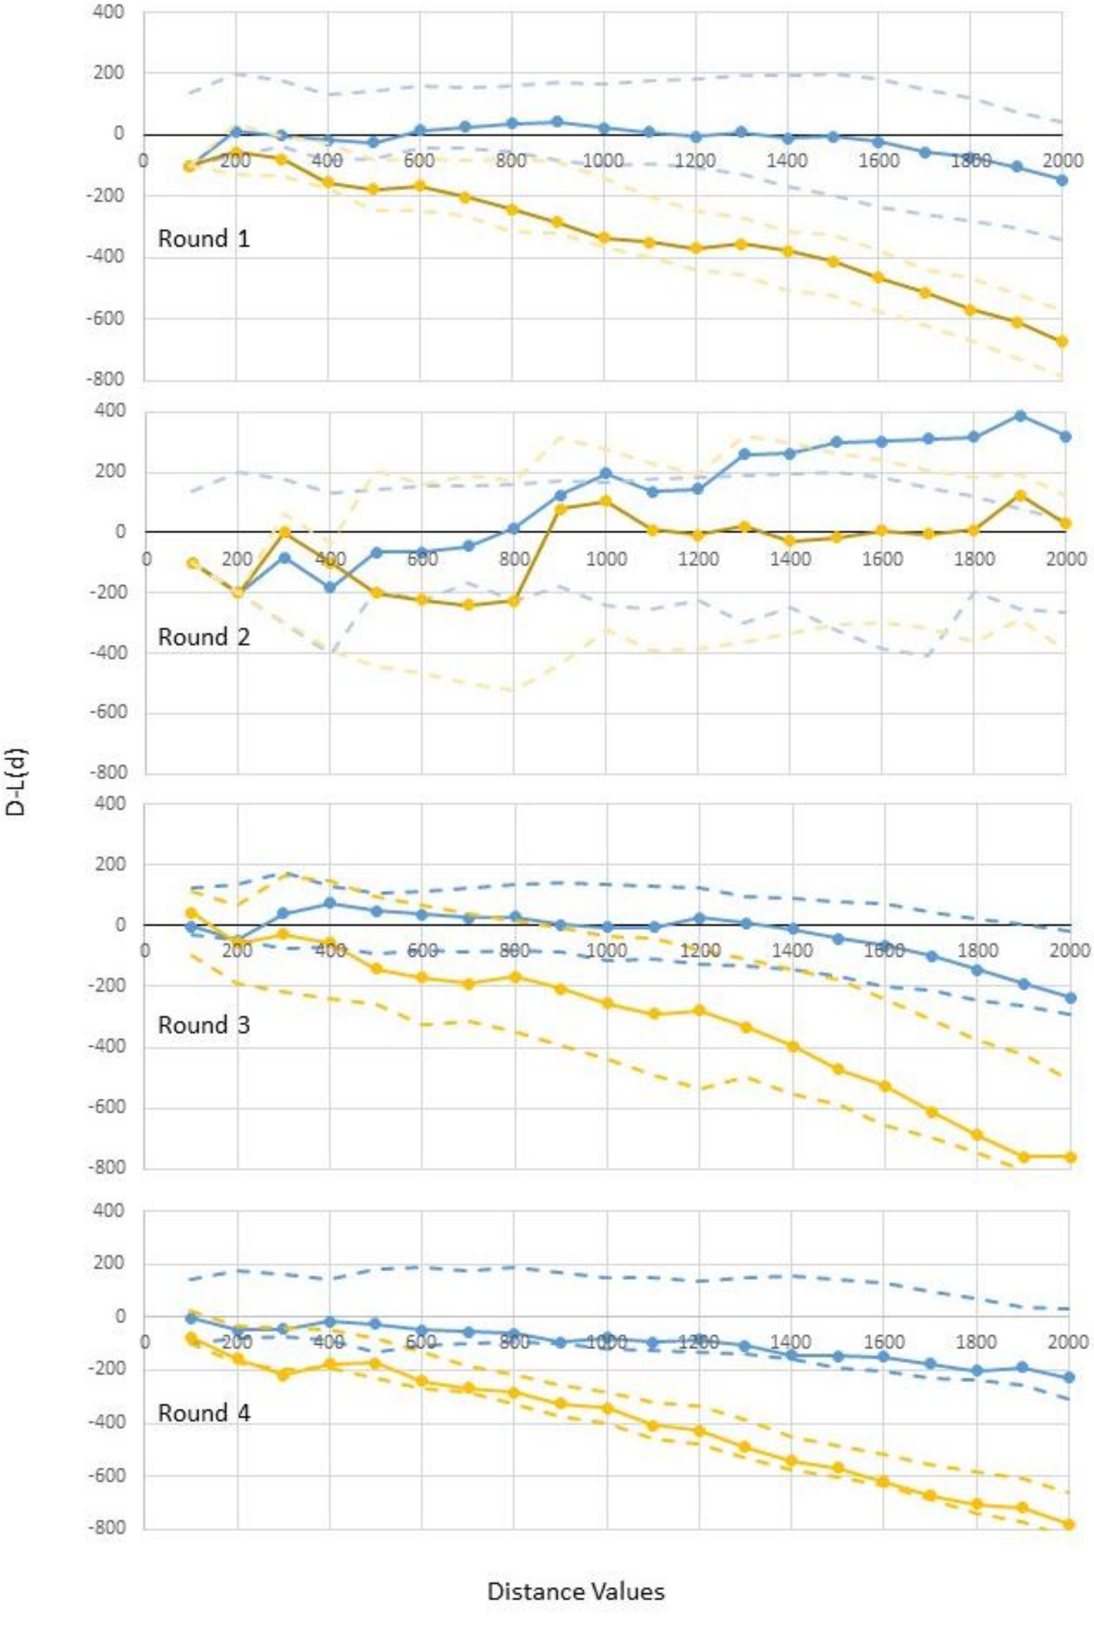
The carcasses were mapped with respect to removal time to assess whether or not the placement affected scavenging time. We then performed several spatial analyses to test whether the removals rates were spatially clustered. The first test was a Ripley's K-function analysis. We used the variance stabilized Ripley's K function represented by the following equation:

$$L(d) = \sqrt{\frac{A \ \sum_{i=1}^{n} \sum_{j=1, j \neq i}^{n} k(i,j)}{\pi n(n-1)}}$$

- Where d is the distance
- n is the number of features
- A is the total area of the features
- K_{ij} is a weight

This test measures deviations from spatial homogeneity. The carcass locations themselves were first analyzed, and then the analysis run using the time to carcass removal as the weight. The parameters used for the analysis were 20 distance bands ranging from 100 to 2000 meters using the sample area as the total area. A simulation of points (mirrors of points near the edges) outside the study area was performed to correct for edge effects and computed a confidence interval using 99 simulated samples. If the data are homogenous, the plot of d versus L(d) - d should follow the horizontal zero axis. A negative value of L(d) – d indicates spatial regularity (rather than randomness), while a positive value indicates clustering (Dixon 2002). We used the simulated confidence intervals to test for statistical significance. Because the sampling frame differed between Round 1 and 4 (more blocks were included in later rounds because construction had completed), analyze all rounds cannot be analyzed together. For Round 1, 3, and 4, analysis of the weighted data indicates more of a regular distribution of time to removal rather than clustering (Figure 6), but not statistically significant based on our constructed confidence intervals. In Round 2, the actual placement of carcasses showed statistically significant evidence of clustering at distances greater than 1200 meters (Figure 6). The weighted analysis did not indicate clustering using the Ripley's K function.

Figure 6. Results of Ripley's K Function analysis of spatial homogeneity for Round 1-4.



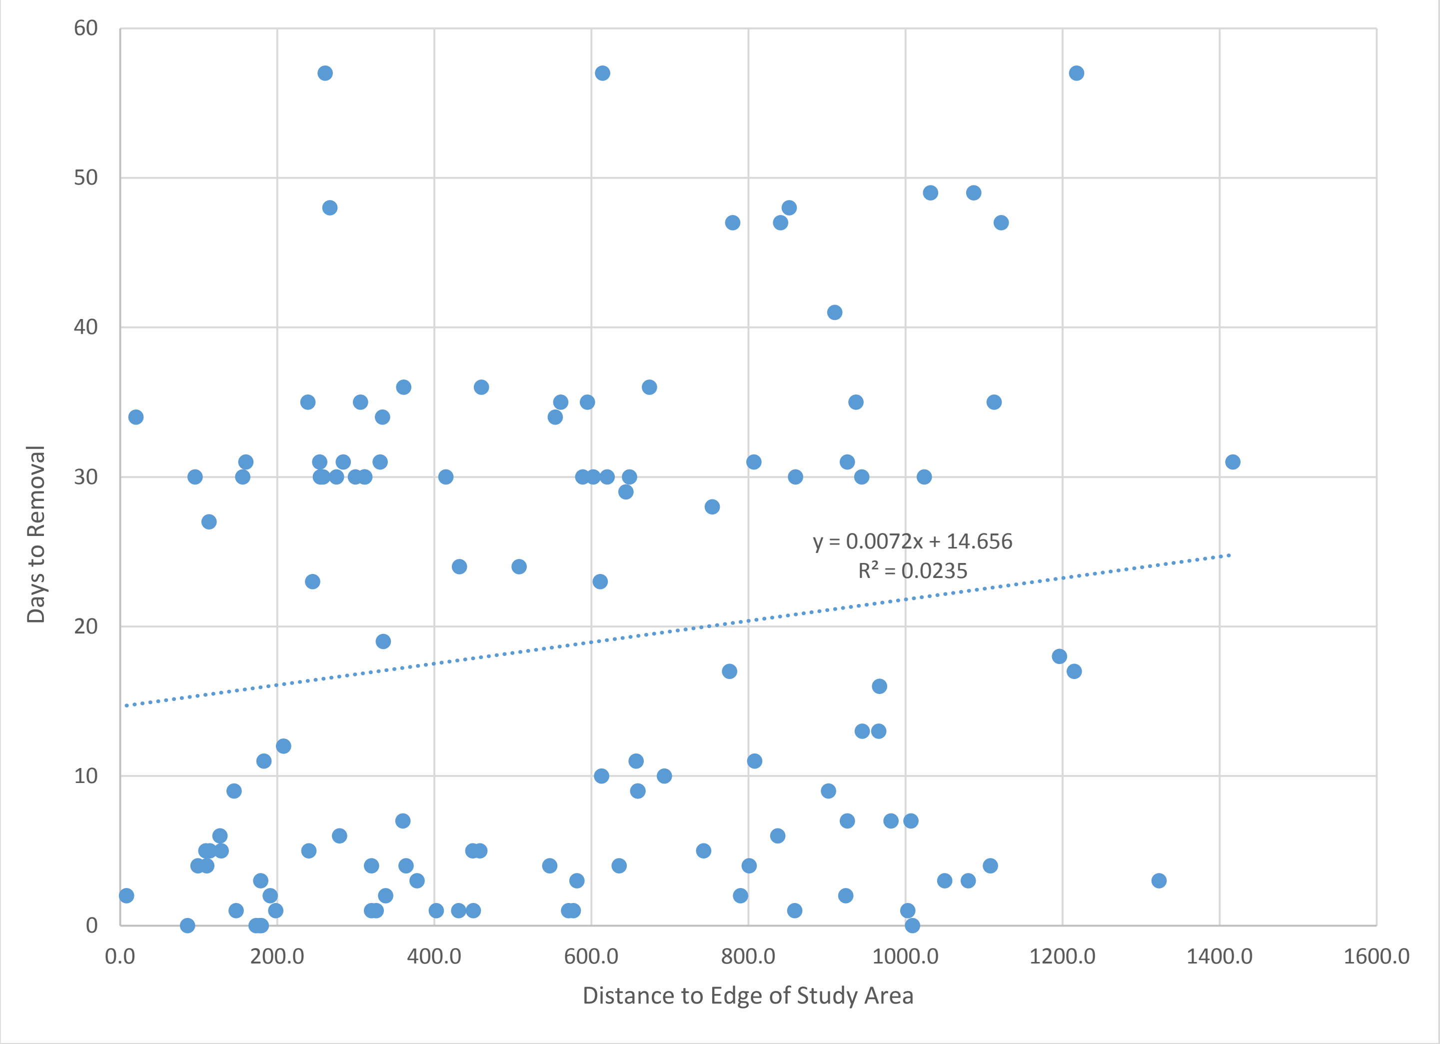
Spatial data was additionally analyzed with the Global Moran's I and the Getis-Ord General G statistic using ArcGIS 10.2 Software. Both are tests of spatial autocorrelation, while the General G will give an idea of clustering of either high or low values (ESRI 2012). In Rounds 1,3, and 4 there was no indication of clustering based on removal times. In Round 2, there was strong evidence of clustering using the Global Moran's test using both Inverse Distance Weighted and Zone of Indifference spatial relationships (Table 3). The Z scores of these tests during Round 2 are likely due more to the perception of clustering during placement rather than an effect of location on removal rates. In other words, it seems that the random placement of carcasses during Round 2 resulted in a clustering of carcasses spatially; however, there was not a clustering of removal times spatially.

Table 6. Results of tests of spatial autocorrelation.

Statistic		Global Moran's I		Getis-Ord General G
Spatial Relationship		Zone of Indifference	Inverse Distance Weighted	Inverse Distance Weighted
Round 1	Threshold Distance	1600	657	657
	Index Value	0.01726	0.062591	0.000265
	Z-score	1.220955	0.60901	-0.130234
	P-value	0.222103	0.542518	0.896381
Round 2	Threshold Distance	1600	1000	1000
	Index Value	0.76932	0.256895	0.000559
	Z-score	2.455789	2.809031	1.404347
	P-value	0.014058	0.004969	0.160215
Round 3	Threshold Distance	1600	755	755
	Index Value	-0.037919	0.124960	0.000244
	Z-score	-0.058703	1.094232	-0.200562
	P-value	0.953189	0.273853	0.841041
Round 4	Threshold Distance	1600	898	898
	Index Value	-0.101823	-0.049867	0.000223
	Z-score	-0.718858	-0.092056	-0.895708
	P-value	0.472228	0.926654	0.370409

Finally, the distance to the edge of the study area were compared to the removal times to see if carcasses near the edge were removed at a different rate from those toward the center (Figure 8). There was not a significant linear relationship between distance to the edge and days to removal (R2 = 0.02).

Figure 7. Comparison of distance to edge of study area and days to carcass removal.



Discussion

Effectiveness of Game Cameras

Game cameras were used to document scavengers and determine removal times due to scavenging events. While game cameras were successfully used for their intended purpose, there are some factors and limitations to consider when using them for Carcass Persistence Trials. Carcasses often become dismembered during scavenging events and remaining body parts evidence a fatality event although the majority of the carcass may have been removed. The photo sequence below (Figure 9 and Figure 10) captures a Common Raven removing a small-sized trial specimen but does not capture the fact that a wing was left behind, persisting as a detectable fatality for two additional days, until a wind event on 5/11/2014 removed it from the Sample Area.

Figure 8. First of two photos documenting the removal of a small-sized trial specimen by a Common Raven. Game cameras did not capture the fact that wing feathers persisted as a feather spot (detectable fatality) until a wind event two days later.

Figure 9. Second of two photos documenting the removal of a small-sized trial specimen by a Common Raven. Game cameras did not capture the fact that wing feathers persisted as a feather spot (detectable fatality) until a wind event two days later.

The persistence of dismembered body parts are not readily captured by game cameras and ground-based monitoring must be implemented in conjunction with game cameras to ensure that removal rates (carcass no longer detectable) are accurately determined. Additionally, game cameras require routine checks to ensure proper functioning and to assess whether or not trial specimens remain within the field-of-view after a scavenging or wind event.

Game cameras remained operational, even when trial specimens were not present, in an effort to determine whether or not Common Ravens formed an association between cameras and a food subsidy. A photo review of cameras with and without carcasses present determined that Common Ravens did not associate cameras with a food subsidy as this species was never documented at a camera location without a carcass present. Kit fox, however, were incidentally detected at camera locations especially after a carcass had been removed. This was most noticeable during Round 3 during which kit fox scavenging rates were at their highest. Kit fox were rarely detected at cameras prior to placement of carcasses. Incidental photo capture was also high for other non-carnivorous mammals such as black-tailed jackrabbit (*Lepus californicus*). It is likely that the smell of the old carcass, rather than the presence of a camera resulted in return visits by kit foxes.

Return visits by scavengers (kit foxes) coupled with the inability of the camera to adequately capture feather spots and severely disarticulated carcasses would also present a challenge when determining actual removal times in the absence of ground-based monitoring. If monitoring were performed solely by cameras, researchers may mistakenly assume that carcasses are still detectable after they have been fully removed due to visits to the area by kit foxes.

Scavenger Effects on Carcass Detectability

The scavenging of trial specimens was a main factor influencing removal rates and carcass detectability. In some instances, scavenging events temporally increased the detectability of a trial specimen by spreading the remains over a larger area (Figure 10).

Dismemberment was more common in larger specimens that are not easily carried away by the scavengers present within the Study Area. Trial specimens within the small size class were often removed, without a trace, in a single scavenging event.

The activities of one scavenger did not deter others. Many of the large and medium carcasses were scavenged by multiple species over the course of the trial period. Even attempts to relocate carcasses were ineffective at detouring the competition (Figure 11).

During carcass searches, field surveyors should be careful to associate dismembered remains to a particular carcass in an effort to avoid double-counting fatality events.

Figure 10. A medium-sized trial specimen is picked apart by a scavenger, increasing the detectability of this carcass by spreading it across a larger area.

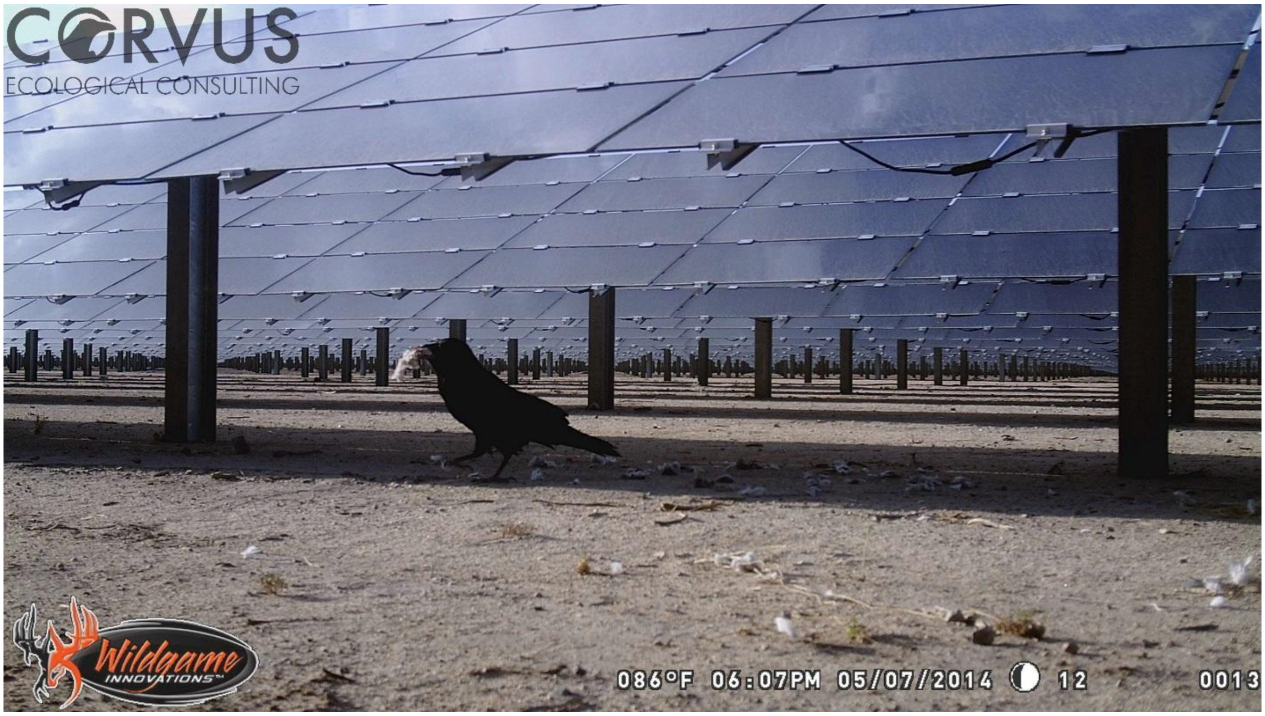


Figure 11. A kit fox is captured by game cameras on top of a solar panel where ravens had dropped a trial specimen.

Size Class Assessment

Data from the three rounds indicates that variation in removal rates among different size classes of carcasses can be expected. During most trials, the small carcasses were removed at a much faster rate than either medium or large. Small carcasses were generally removed completely in one event while the medium and large carcasses were often dismembered or plucked in place. As was stated earlier, these actions generally made a carcass temporally more detectable as it was scattered over a large area. Over time, however, wind events carry the feathers and wings and could complicate accounting of naturally occurring carcasses. It is also important to note again that for the purposes of analysis, we concluded our trials at 30 days. In reality, some of our large carcasses were clearly detectable upwards of 100 days post placement.

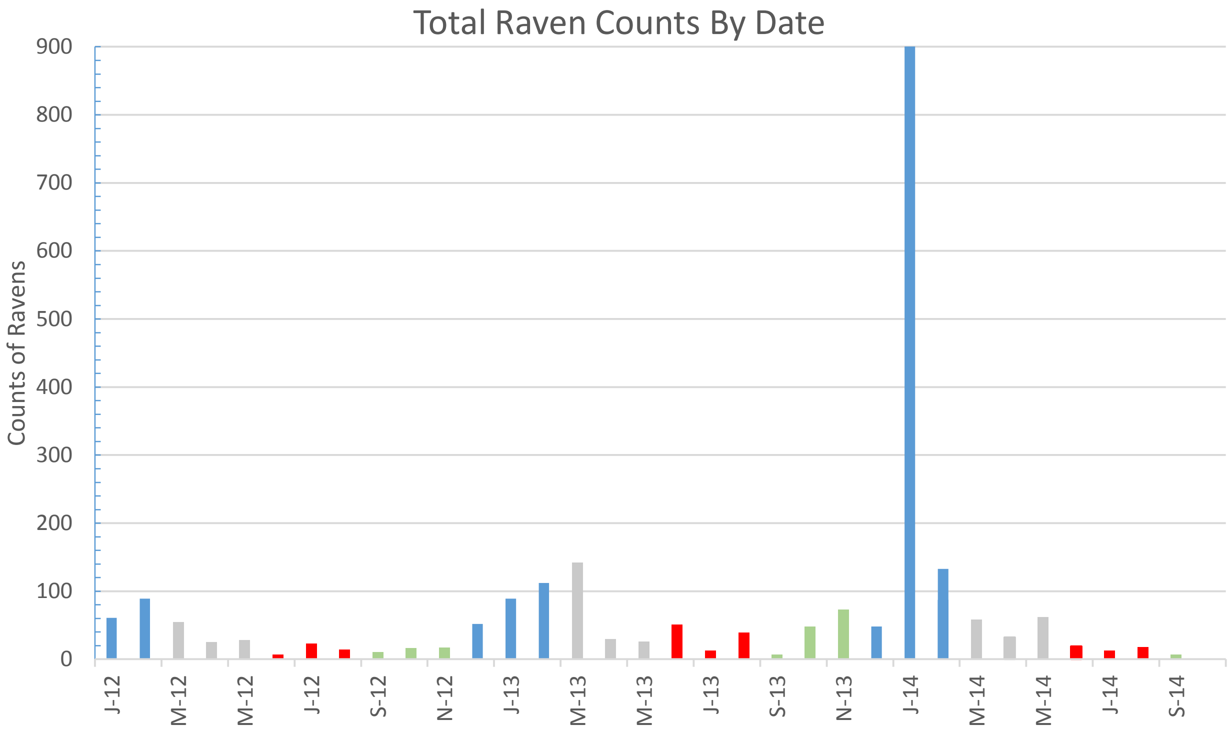
Species composition from incidental fatality data collected at the Desert Sunlight Solar Farm was assessed in an effort to categorize these data into corresponding size classes. Assessed incidental data included 133 instances resulting in fatality over the course of thirty-three months (between September 2011 and June 2014). Of the 133 carcasses documented, 26% would be classified as large (larger than an American Crow, *Corvus brachyrhynchos*), 33% would be classified as medium (approximately American Kestrel, *Falco sparverius*, to American Crow size), and 41% would be classified as small. The most frequently encountered carcass species was the Western Grebe (*Aechmophorus occidentalis*), accounting for 15 total fatalities. Western Grebes would be classified as a large carcass under the above classification scenario.

Seasonal Differences in Removal Times

Carcasses were placed during 4 distinct rounds in order to capture seasonal differences in scavenging and removal rates. With our relatively small sample sizes, we were unable to detect significant differences in removal rates except when comparing the small carcass size class between rounds 1 and 3. Round 3 took place during the winter months and kit foxes were the dominant scavengers captured by our game cameras. Another distinction of the trial in Round 3 is that it took place immediately upon the conclusion of the construction phase at the facility. It is possible that the kit fox population had previously been subsidized by human activities associated with the construction phase (trash etc.) and were motivated to patrol the facility for resources once those subsidies were removed. We did not see the same quick removal times in Round 4, so it is unlikely that prior to Round 3, human presence on the facility deterred their behavior. Further trials are needed in order to determine if it is a natural biological cycle that caused this increase in scavenging times.

Raven-specific surveys are conducted monthly to support requirements of the Project's Raven Management Plan. The data collected through these efforts shows a trend related to temporal fluctuations in the abundance of Common Ravens within the Chuckwalla Valley (Figure 9). Common Ravens were responsible for scavenging trial specimens and carcass persistence rates are likely to fluctuate with changes to the presence of Common Ravens. These data indicate that raven presence could also have been a factor in the quick removal times during Round 3.

Figure 12. Survey data shows a trend related to temporal fluctuations in the abundance of Common Ravens within the Chuckwalla Valley.



Wind Events

Inedible body parts such as: wings, body feathers, feet and legs would often remain detectable, post scavenging, until a wind event occurred. Wind events were most often responsible for removing evidence of fatalities including dismembered body parts and feather spots. There were some instances were wind was responsible for relocating trial specimens within the Sample Area. Wind was responsible for relocating two small-sized trial specimens, one was moved 17 meters (DS-TS-04) and the other was moved 10 meters (DS-TS-11). Major wind events, such as one which occurred on 5/11/2014 were responsible for the removal of dismembered parts and feather spots. Figures 10 and 11 below show a wind event captured by a game camera on 5/11/2014, when onsite weather stations recorded wind gusts as high as 50 miles-per-hour. The facility also experienced a tornado on 21 April 2015 which damaged several solar panels. While none of the trial specimen were affected by this event, repeat occurrences of wind events of this magnitude will likely have an effect on carcass detectability.

Figure 13. Photo 1 of 2 documenting a wind event on 5/11/2014 that spanned approximately 3.5 hours and removed three of the fifteen group 1 trial specimens from the Sample Area.

Figure 14. Photo 2 of 2 documenting a wind event on 5/11/2014 that spanned approximately 3.5 hours and removed three of the fifteen group 1 trial specimens from the Sample Area.

Search Effort and Carcass Persistence During Ground-based Monitoring

Ground-based monitoring efforts, in conjunction with remote game cameras, were used to assess and successfully determine carcass removal rates within the Sample Area. The level of effort undertaken by field workers was a factor in determining removal rates. Wind events and scavengers were the two primary factors influencing the detectability of trial specimens and it was not uncommon for trial specimens to be moved -- but not removed – within the Sample Area. Search efforts implemented during ground-based monitoring sometimes resulted in the detection of trial specimens at locations other than the point of their original placement; and these carcasses remained detectable when they might have been recorded as “removed” without an additional search effort.

Given the size of the Sample Area (2,097 acres), a comprehensive survey was not possible during scheduled ground- based monitoring efforts. A trial specimen was recorded as, “removed” once it was no longer detectable at the point of original placement or within 25 meters of the original placement. Consequently, the determination of removal rates resulting from this effort should be considered conservative since it is possible that displaced trial specimens remain detectable somewhere within the Sample Area.

Eight days following the conclusion of trial period 1, a trial specimen was incidentally encountered in a storage area where it persisted as a feather spot, detectable under a stack of pallets. This finding was not included in these results but provides support that these removal times are conservative.

Desert Sunlight Solar Farm Spring 2015 Monitoring Report Comment Response Document

Business confidential

December 9, 2015

The following is a list of comments made on the Desert Sunlight Spring 2015 Post-Construction Monitoring Report dated July 17, 2015 as well as responses to those comments. We have also addressed comments made during the July 21, 2015 TAG meeting.

Agency Comment Number or Section-Line number reference	Agency Comment	Response from Desert Sunlight – reference new section
FWS1	Pre-spring survey data are not meaningful and should probably be excluded. Please describe how these data were or were not incorporated into estimates.	Pre-spring carcass search data have been removed from the report and the FWS request to remove data memorialized in section 1.3.
FWS2	Please record and report the time of the surveys. This will help determine if the surveys can be used to predict nocturnal vs. diurnal mig behavior.	We have added the following text to section 2.1.2: All searches take place during daylight hours from 06:30 to 17:00.
FWS3	Please include median times and/or a curve showing # remaining over time.	We have included a new figure (Figure 7) reporting proportion of trial carcasses remaining as a function of days since placement.
FWS4	Please describe how detectability is being handled for the 25% being surveyed from a distance.	We added the following text to the footnote in Table 1: Fatality rates estimated for sections of the fence that are sampled were extrapolated to sections of the fence where the standard monitoring protocol cannot be used, as described in section 4.2.6 of the approved Desert Sunlight BBCS.
FWS5	Based on persistence trials? I suggest putting the carcass and searcher efficiency trials first since they dictate the timing of the standardized carcass searches.	We inserted the following text in section 2.1.1: As specified in the approved Desert Sunlight BBCS, the average search interval…
FWS6	This is not clear. Please clarify how sampling was affected by the damage from the tornado.	We revised text in section 2.1.1 to read: Six arrays were visited seven times from the beginning of the spring season until the tornado occurred on April 21, 2015; 3

Agency Comment Number or Section-Line number reference	Agency Comment	Response from Desert Sunlight – reference new section
	Further, articulate what was done to replace the arrays that were damaged in the sampling scheme.	weeks elapsed before the six damaged arrays were replaced with arrays in the solar field that were not affected by the tornado. During this 3-week period, Desert Sunlight LLC remained in contact with the BLM as details on access limitation developed. Once it was determined that access to damaged arrays would be limited for a longer time period, six replacement arrays were identified; five were visited twice and one was visited once. Replacement arrays were identified by choosing a random sample of non-damaged arrays within the same block that contained the original arrays that were damaged by the tornado.
FWS7	Was the carcass then processed and removed? Please clarify the carcass processing procedure.	We inserted text in section 2.1.2 to clarify: Once a carcass was detected, it was then photographed, and data were recorded according to specifications outlined in section 7.2.5 of the approved Desert Sunlight BBCS. Carcasses detected before amendment of the WEST California Scientific Collecting Permit (Permit # 3790) were covered and secured in place until permission was granted from California Department of Fish and Wildlife to handle carcasses on April 21, 2015. Since that date, all carcasses have been retrieved from their location on the ground, labeled, and placed in a freezer on site.
2.1.2 L13-14	Text inserted:"…with observers looking toward the center of the array."	Revision accepted
FWS8	Please describe how this is this accounted for in the overall estimates.	We inserted text in section 2.1.2 to clarify: As specified in section 4.2.6 in the approved Desert Sunlight BBCS, we assume that fatality rates are similar between the portion

Agency Comment Number or Section-Line number reference	Agency Comment	Response from Desert Sunlight – reference new section
		of fence that was searched and the portion that was not.
FWS9	Again, please describe how this was accounted for in the estimates.	We inserted text to section 2.1.2 to clarify: As specified in section 4.2.6 in the approved Desert Sunlight BBCS, we assume that fatality rates are similar between the portion of fence that was searched and the portion that was not.
FWS10	This doesn't seem valid, given the site differences in these segments of the fences.	We revised text in section 2.1.2 to address: Fatality rates estimated for sections of the fence that were sampled were adjusted to account for the proportion of fence not sampled with the standard monitoring protocol, as specified in section 4.2.6 of the approved Desert Sunlight BBCS.
FWS11	The Service disagrees with this assumption. If it's under the line, the better assumption is that it was caused by the line and a scavenger subsequently discovered the carcass.	By assigning a suspected cause of death as unknown, collision with project infrastructure is not being discounted as a potential cause – it only means there is insufficient evidence to assign a specific cause. Detections made beneath the line could also potentially be a result of predation by raptors perched on the line. We revised text in section 2.1.2 to clarify: For each detection, a suspected cause of death or injury was assigned based on evidence available from the detection, evidence available on Project infrastructure, and proximity of the detection to Project infrastructure. Detections that had evidence of scavenging and lacked evidence on Project infrastructure were assigned as "unknown" because it cannot be determined whether the event was caused by predation or interaction with project infrastructure. Detections that were intact (i.e., no evidence of scavenging) and

Agency Comment Number or Section-Line number reference	Agency Comment	Response from Desert Sunlight – reference new section
		located in close proximity to Project infrastructure (e.g., found directly beneath overhead lines) had a suspected cause of death attributed to the respective Project component. However, it should be noted that there is substantial uncertainty associated with cause of death assignments because no events were directly observed. Detections assigned to the “unknown” category were included in fatality estimates if they were located within standardized carcass search areas.
2.2 L1	Text inserted:”…for the truncated winter season and…”	Revision not accepted due to exclusion of winter survey data.
FWS12	This number of carcasses is extremely low. Did you do a power analysis?	The sample size used for spring carcass persistence trials was compliant with the sample size specified in the Desert Sunlight BBCS approved December 2014. The number of carcasses placed for carcass trials is a balance between having a reasonable sample to estimate carcass removal rates, and subsidizing scavengers and potentially creating artificial scavenger dynamics at the Project. The sample size used was decided upon after extensive conversations with Amy Fesnock at BLM. Future seasonal reports and the annual report will pool information on carcass persistence and retrospectively test for seasonal effects using an information-theoretic modeling approach.
FWS13	With such a low number of carcasses this is unlikely to be a problem.	It is unclear what revisions are being requested, if any. Total sample size of carcasses placed at the Project (for all bias trials) is n = 210 per season (carcass persistence trials: 30 along gen-tie and 30

Agency Comment Number or Section-Line number reference	Agency Comment	Response from Desert Sunlight – reference new section
		within the Project fence; searcher efficiency trials: 60 along gen-tie [30 in each visibility strata], 60 within the arrays [30 in each visibility strata], and 30 along the fence). We believe this is a large enough number, especially relative to the number of non-trial detections being made at the Project, that carcasses should be placed only a few at a time throughout the season.
FWS14	Does this mean n=15 was put out twice for the Feb trials? Please clarify. Also, are the gen-tie carcasses outside the project fence? If so, there seem to be two difference scavenger communities being tested.	We revised text in section 2.2.1 to clarify: Carcass persistence trials within the solar arrays and fence were initiated two days earlier in February than trials along the gen-tie line.
FWS15	Please describe the interval that carcasses were checked. Is there a reason that they are not checked daily, particularly during the first week?	Please refer to section 2.2.1, where the frequency of carcass checks is described: Carcasses without trail cameras were visited and photographed once per day for the first four days, and then every three to five days until the end of the monitoring period; Periodic ground-based checking of carcasses with trail cameras also occurred to guard against misleading indicators of carcass removal, such as wind blowing the carcass out of the camera's field of view. This schedule has proven reliable in allowing persistence distributions to be estimated.
FWS16	This does not seem true. If the carcass is not there on day 10, they it has been removed before that and would not be available during some portion of the interval. Please clarify how this uncertainty affects the analysis. There should probably be a convention for determining the removal data	We have inserted additional text in section 2.2.2 to address data censoring: Because carcass persistence data were censored, persistence was analyzed using methods that can accommodate censored data and still produce unbiased estimates of the probability of persistence (Therneau 2015,

Agency Comment Number or Section-Line number reference	Agency Comment	Response from Desert Sunlight – reference new section
	(i.e., the mid-point). In general, the interval should be kept as short as possible.	Therneau and Grambsch 2000). USGS-developed fatality estimator software (Huso et al 2012) was used to fit survival models to the censored carcass persistence data.
FWS17	How does "censored" status affect the analysis?	We have inserted additional text in section 2.2.2 to address data censoring: Because carcass persistence data were censored, persistence was analyzed using methods that can accommodate censored data and still produce unbiased estimates of the probability of persistence (Therneau 2015, Therneau and Grambsch 2000).
FWS18	Has this been evaluated as adequate to determine searcher efficiency for a single strata? Please provide justification for small sample size.	We revised text in section 2.3.1 to clarify how sample sizes were determined: In the solar arrays, one set of searcher efficiency trials (n = 15 small birds, 10 medium birds, and 5 large birds as agreed upon in section 7.4 of the approved Desert Sunlight BBCS) was conducted in each strata. It is also standard practice to pool data across seasons or other initial strata if differences are not detected. For example, pooling searcher efficiency data across seasons is likely and reasonable given the small changes anticipated in ground cover among seasons.
FWS19	Is searcher efficiency tested for each observer? Please provide these results along with an indication of variation in searcher efficiency across observers.	As agreed upon in the approved Desert Sunlight BBCS, "Searcher efficiency will be summarized for each individual searcher but to avoid needlessly inflating the variance of the estimate, individual searcher effects will not be included in the fatality

Agency Comment Number or Section-Line number reference	Agency Comment	Response from Desert Sunlight – reference new section
		estimation model." Section 7.4, p.29 (DSL BBCS). Estimates of individual searcher efficiency will be summarized for the annual report, but are beyond the scope and schedule of the seasonal report. We have added a list of observers and the number of searcher efficiency trials available for each observer to find during the spring season in section 3.7.
FWS20	Is sample size adequate to detect a difference between visibility categories?	Evaluation of differences in searcher efficiency between visibility categories will be made with additional data available in the annual report. This level of analysis is beyond the scope and schedule of the seasonal report.
FWS21	Shouldn't the curves then be for 35m and 70m?	We have revised the title for Figure 5 for clarity: Estimated detection probabilities for bird carcasses by size class during spring 2015 (including February) at the Desert Sunlight Solar Farm Project, Riverside County, California. Distance sampling was used when searching solar arrays only. Average probability of detection over 70-m (arrays relying on a 35-m viewshed) and 140-m (arrays relying on a 70-m viewshed) panel rows in solar arrays are presented. Further, we have added sample sizes for 70-m and 140-m arrays in Table 2.
FWS22	How does this relate to the curves above? Detectability for small birds drops off before 70 m and presumably is near zero for greater than 70 m.	We have revised section 2.3.2 to clarify how average searcher efficiency was estimated: The mean value of the detection curve is the integral of the detection function calculated between 0-m and the maximum survey distance (w; half the width of the solar array row), divided by the maximum

Agency Comment Number or Section-Line number reference	Agency Comment	Response from Desert Sunlight – reference new section
		survey distance: $p = \frac{\int_0^w f(x)dx}{w}$ where f(x) is the detection function evaluated at distance, x. And, The weighted average searcher efficiency is calculated based on the number of panel rows of each length in the survey sample: $p_{weighted\ average} = \frac{n_{70}}{n} \times \int_0^{35} f(x)dx + \frac{n_{140}}{n} \times \int_0^{70} f(x)dx,$ where n_{70} is the number of 70-m rows in the sample, $n_{140}$is the number of 140-m rows in the sample, and *n* is the total number of rows in the sample.
FWS23	Was proximity to project features evaluated? Please describe how this information was utilized. Proximity distances may provide insights into which features may pose the greatest risks.	These data are reported in the monthly Avian Injury & Mortality Report. These data will be reported in the annual report but are beyond the scope and schedule of seasonal reports.
FWS24	Since scavenger rates are so high, this definition too easily categorizes carcasses as unknown. Low levels of scavenging should not exclude birds from a more thoughtful evaluation of the cause of the mortality. Other criteria should be considered, including patterns of disturbed dust on solar panels, proximity to a feature with collision risk. Such a blanket categorization, probably masks useful information.	Other criteria are considered. We revised text in section 2.1.2 and the footnote of Table 4 to clarify: Suspected cause of death or injury was assigned based on evidence available from the detection, evidence available on Project infrastructure, and proximity of the detection to Project infrastructure. Detections that had evidence of scavenging and lacked evidence on Project infrastructure were assigned as “unknown” because it cannot be determined

Agency Comment Number or Section-Line number reference	Agency Comment	Response from Desert Sunlight – reference new section
		whether the event was caused by predation or interaction with project infrastructure. Assignments to "suspected cause of death" categories reported in the DSL spring 2015 post-construction monitoring report is consistent with what has been reported in previously-submitted monthly SPUT reports. Per recent discussions, we are looking for additional guidance provided with the SPUT report on making determinations of suspected cause of death.
Table 4 footnote	Text revised: "…in the absence of a completed necropsy,	Revision not accepted. Definitive cause of death is not determined for 100% of necropsies. WEST biologists look for evidence of collision on Project infrastructure, but there is very little information available in terms of evidence suggesting cause of death for the vast majority of detections, and this the case for most all bird fatality studies at renewable energy sites.
FWS25	Spatial distribution of different taxonomic groups should be discussed, particularly as more data come in.	Spatial distribution of carcasses is reported in Table 2. To include discussion of this topic at present would not be meaningful, and it will be addressed in the annual report.
FWS26	This is a good (and more conservative) practice, even if the dove were successfully released, because the viability of the released bird is unknown.	No revisions made.
FWS27	This looks like there may be an effect on persistence time from being outside the fence. This may be due to differences in the scavenger community. Was this tested?	We did not test the scavenger community, but we did test the hypothesis that carcass persistence time inside the fence was different than persistence time outside the fence by comparing models of carcass

Agency Comment Number or Section-Line number reference	Agency Comment	Response from Desert Sunlight – reference new section
		persistence with and without a covariate for project component using an information-theoretic framework. The best model supported the hypothesis that persistence times were specific to project component, hence we reported two different estimates of persistence. We have revised text in section 3.6 to clarify: The model with lowest AICc score is typically chosen as the “best” model relative to other models tested; however, any model within two AICc points of the best model is considered competitive with the best model (Burnham and Anderson 2004). The best model had a ∆AICc value of 0.77 and included effects of carcass size (small, medium or large), and location (solar arrays/fence or generation-tie line) with a Weibull-distributed removal time, but no effect of season. Estimates of carcass removal time and persistence probabilities are reported from the best model in Table 5.
FWS28	How was this broken down by visibility categories and size classes? See Appendix C?	A breakdown of sample sizes for searcher efficiency trials is found in section 2.3.1. WEST will report more detailed results regarding how many were available to be found by category in the annual report. This level of detail is beyond the scope and schedule of the seasonal reports.
FWS29	Shouldn’t both season and habitat visibility class be evaluated?	That will be tested in future seasonal reports. Removed paragraph as it is unnecessary for the report.
FWS30	Again, a more thoughtful evaluation of cause of mortality should be done to reduce the number of unknowns. In particular, mortalities associated with project features	Please see revised text in section 2.1.2 regarding assignment of suspected cause of death.

Agency Comment Number or Section-Line number reference	Agency Comment	Response from Desert Sunlight – reference new section
	that may present a collision risk are probably better categorized as collisions (i.e., solar panels and overhead electrical lines).	
FWS31	This is the same as for Genesis.	This number has been revised as a result of dropping carcass search data from February.
FWS32	This table/appendix requires more explanation.	We have revised the table title and added footnotes for clarification.
TAG Meeting Topics		
	Definition of overhead lines	We revised text throughout the report to clarify; generation tie line and medium voltage overhead lines (associated with the solar field) are now reported separately.
	Sample units associated with overhead collector lines vs. sample units not associated with lines	We revised Figure 2 to include information about sample units that are and are not associated with overhead lines. We included a new table (Table 3) that presents information on the extent of line-associated and non-line-associated arrays in the solar field, representation in the sample, and number of detections associated with each type of array.

Desert Sunlight Solar Farm Summer 2015 Monitoring Report Comment Response Document (draft)

Business Confidential

February 2, 2016

The following is a listing of comments made on the Desert Sunlight Summer 2015 Post-Construction Monitoring Report dated October 15, 2015 as well as responses to those comments.

Agency Comment Number or Section-Line number reference	Agency Comment	Response from Desert Sunlight – reference new section
FWS1	Please explain why carcass persistence is influenced by project component.	"During the reporting period, carcass persistence was influenced by carcass size and Project component" is a standard way of reporting model results where AIC supported a best model that included main effects of carcass size and Project component. We have added text in the executive summary and Section 3.6 about why this pattern was observed: The difference in carcass removal times between Project components is because scavengers likely occur in higher densities outside the perimeter fence.
FWS2	Please report median removal times and a figure showing the curve of # remaining over time.	We have included median removal times in the Executive Summary and Table 6. See Figure 7 for the curve of proportion of trial carcasses remaining as a function of days since placement.
FWS3	Is this the searcher efficiency averaged for all observers? What is n?	All searcher efficiency rates are averaged over searchers, as stated in Section 7.4 of the approved Desert Sunlight BBCS. For searcher efficiency rates at the arrays in summer we pooled all available searcher efficiency trial data over all seasons because we found no effect of season on searcher efficiency rates supported by our AIC modeling approach. However at the fence and gen-tie, there were significant seasonal differences so searcher efficiency

Agency Comment Number or Section-Line number reference	Agency Comment	Response from Desert Sunlight – reference new section
		trial data from the summer only was used at these components. See section 3.7 for text revised for clarity. We have also provided information on the sample sizes per individual
FWS4	IMPORTANT: WEST has said that it modified the Huso estimator, and despite several requests, those modifications have not been shared with the agencies. Until we understand what changes to the code were made, we are reserving judgment on these results.	Revision to the Huso estimator is strictly to the searcher efficiency component of the model. Huso (2010) uses a binomial model to estimate searcher efficiency; the current analysis calculates searcher efficiency via a distance-sampling model, which is detailed in this report (the formula provided for p in Section 2.3.2). Otherwise the model is not modified. We have revised the Executive Summary to include an explanation of the modification, as follows: Using the Huso (2010) fatality estimator model, modified to accommodate a distance-sampling approach to the estimation of searcher efficiency, Text has also been added to Section 2.4 to clarify how the modified estimation of searcher efficiency was used to estimate fatalities.
FWS5	This supports increased frequency for this component.	Any changes to the monitoring plan will be discussed with the TAG.
FWS6	Is this relevant? Please delete. All projects are reporting all mortalities via SPUT reporting regardless of how many.	Revision accepted.
FWS7	Please describe how detectability is being handled for the 25% being surveyed from a distance.	We added the following text to the footnote in Table 1: Fatality rates estimated for sections of the fence that are sampled were extrapolated to sections of the fence where the standard monitoring protocol cannot be used, as described in section 4.2.6 of the

Agency Comment Number or Section-Line number reference	Agency Comment	Response from Desert Sunlight – reference new section
		approved Desert Sunlight BBCS.
FWS8	Please record and report data on the time of the surveys. This will help determine if the surveys can be used to predict nocturnal vs. diurnal mig behavior. Raw data sheets and GIS files should be submitted with each report.	We have added the following text to section 2.1.2: All searches take place during daylight hours from approximately 530 am to 5 pm. In the summer searches took place from 5:40 am to 2:08 pm Transfer of data files will be discussed by the TAG.
FWS9	Please discuss the effect of the long search interval in relation to the carcass persistence trial data.	We added the following text to Section 4.1: Fatality estimates are influenced by the relationship between carcass removal dynamics and search intervals. In practical terms, longer search intervals reduce average probability that a carcass persists until the next search. In terms of the analysis, this can manifest as a lower probability of persistence through the effective search interval, or an effective search interval that is shorter than the nominal search interval. In either case, the adjustment to carcass counts due to carcass removal dynamics is calculated as (length of effective search interval)/(length of nominal search interval*average probability of persistence through the effective search interval) The adjustment to estimated fatality for carcass removal increases with longer search intervals, and the variance in the estimate may increase, also.
FWS10	Please explain details about how/when the processing occurred in relation to when carcasses were detected.	We revised text in Section 2.1.2 to clarify: As soon as a carcass was detected, it was photographed, and data were recorded according to specifications outlined in

Agency Comment Number or Section-Line number reference	Agency Comment	Response from Desert Sunlight – reference new section
		section 7.2.5 of the approved Desert Sunlight BBCS. Carcasses were then immediately retrieved from their location on the ground, labeled, and placed in a freezer on site.
FWS11	The Service is still concerned that this section of the fence is not being adequately sampled. Mortality rates may be different along this section of the fence.	The current monitoring method and analysis treats this section of the fence as described in the approved Desert Sunlight BBCS. Furthermore, the very low number of detections that have occurred along the fence (n = 5 since monitoring began in Feb. 2015) suggests the fence has not been a significant source of mortality thus far. This approach has been used at wind energy facilities. In addition, a very high proportion of the fence is sampled.
FWS12	The Service disagrees with this assumption. If it's under the line, the better assumption is that it was caused by the line and a scavenger subsequently discovered the carcass.	By assigning a suspected cause of death as unknown, collision with project infrastructure is not being discounted as a potential cause – it only means there is insufficient evidence to assign a specific cause. Detections made beneath the line could also potentially be a result of predation by raptors perched on the line. We revised text in section 2.1.2 to clarify: For each detection, a suspected cause of death or injury was assigned based on evidence available from the detection, *evidence available on Project infrastructure*, and proximity of the detection to Project infrastructure. Detections that had evidence of scavenging and lacked evidence on Project infrastructure were assigned as "unknown" because it cannot be determined whether the event was caused by predation or interaction with project infrastructure. Detections that were

Agency Comment Number or Section-Line number reference	Agency Comment	Response from Desert Sunlight – reference new section
		intact (i.e., no evidence of scavenging) and located in close proximity to Project infrastructure (e.g., found directly beneath overhead lines) had a suspected cause of death attributed to the respective Project component. However, it should be noted that there is substantial uncertainty associated with cause of death assignments because no events were directly observed. Detections assigned to the "unknown" category were included in fatality estimates if they were located within standardized carcass search areas. This is consistent with approaches used in wind energy studies.
FWS13	This number of carcasses is extremely low. The Service recommends increasing the number of trial carcasses to help reduce the confidence intervals on estimates.	The number of carcasses used for trials is the number outlined in the approved Desert Sunlight BBCS. The annual report will include a sample of 240 carcass persistence trials (4 seasons) plus an additional 30 from Feb. 2015, and this pooled sample will result in increased power to detect differences.
FWS14	With such a low number of carcasses this is unlikely to be a problem.	It is unclear what revisions are being requested, if any. Total sample size of carcasses placed at the Project (for all bias trials) is n = 210 per season (carcass persistence trials: 30 along gen-tie and 30 within the Project fence; searcher efficiency trials: 60 along gen-tie [30 in each visibility strata], 60 within the arrays [30 in each visibility strata], and 30 along the fence). We believe this is a large enough number, especially relative to the number of non-trial detections being made at the Project, that carcasses should be placed only a few at a

Agency Comment Number or Section-Line number reference	Agency Comment	Response from Desert Sunlight – reference new section
		time throughout the season. There needs to be a balance between large sample sizes for estimating fatality parameters and too large of sample sizes to a point of increasing scavengers and bringing in more ravens.
FWS15	Please describe the interval that carcasses were checked. Is there a reason that they are not checked daily, particularly during the first week?	Please refer to section 2.2.1, where the frequency of carcass checks is described: Carcasses without trail cameras were visited and photographed once per day for the first four days, and then every three to five days until the end of the monitoring period; Periodic ground-based checking of carcasses with trail cameras also occurred to guard against misleading indicators of carcass removal, such as wind blowing the carcass out of the camera's field of view. We also added the same language to section 2.2.2 for ease of reference. This schedule has proven reliable in allowing persistence distributions to be estimated.
FWS16	Please clarify how censored data were analyzed and how the analytical methods affected the results. The referenced book is not available to the reader; please provide citation to the agencies. How does the method affect the effective search interval?	WEST has included a copy of the requested citation along with this response matrix. We have revised text in Section 2.2.2 to clarify: It is beyond the scope of this document to provide statistical foundations of censored-data survival models but functions identical to those provided with the USGS-developed fatality estimator software (Huso et al 2012)

Agency Comment Number or Section-Line number reference	Agency Comment	Response from Desert Sunlight – reference new section
		were used to fit survival models to the censored carcass persistence data, and some background is available in the documentation provided with that software. Some additional detail will be provided in the annual report.
FWS17	The Service proposed larger sample sizes for carcass persistence and searcher efficiency trials. Hence, has this been evaluated as adequate to determine searcher efficiency for a single strata? Please provide justification for small sample size.	We revised text in section 2.3.1 to clarify how sample sizes were determined: In the solar arrays, one set of searcher efficiency trials (n = 15 small birds, 10 medium birds, and 5 large birds as agreed upon in section 7.4 of the approved Desert Sunlight BBCS) was conducted in each strata. It is also standard practice to pool data across seasons or other initial strata if differences are not detected. For example, pooling searcher efficiency data across seasons is likely and reasonable given the small changes anticipated in ground cover among seasons. In addition, fewer samples for the large carcasses is justified, given the lower removal rates and the higher detection for that class. See also the response to FWS14.
FWS18	The terminology here is inconsistent with above. Each carcass counts as a trial or a trial consist of n carcasses?	We revised text in Section 2.3.1 to clarify: Thirty searcher efficiency trial carcasses (n = 15 small birds, 10 medium birds, and 5 large birds) were placed along the fence in the only visibility class present on the fence (easy visibility).
FWS19	Is searcher efficiency tested for each observer? Please provide these results along with an indication of variation in searcher efficiency across observers.	As agreed upon in the approved Desert Sunlight BBCS, “Searcher efficiency will be summarized for each individual searcher but to avoid needlessly inflating the variance of the estimate, individual searcher

Agency Comment Number or Section-Line number reference	Agency Comment	Response from Desert Sunlight – reference new section
		effects will not be included in the fatality estimation model." Section 7.4, p.29 (DSL BBCS). Estimates of individual searcher efficiency will be summarized for the annual report, but are beyond the scope and schedule of the seasonal report. We have added a list of observers and the number of searcher efficiency trials available for each observer to find during the spring season in section 3.7. This approach is consistent with other fatality monitoring programs for solar and wind.
FWS20	Please provide an analysis that the sample size is adequate to detect a difference between visibility categories. This result seems to be an artifact of the low sample size.	The power of a particular sample size to detect a difference between visibility categories depends on the magnitude of the difference that exists. We have stratified by visibility category, resulting in a 100% increase in the sample size at the solar arrays and along the gen-tie line. Given the fact that we have been able to detect differences among components at Genesis with the same sample sizes (e.g., a 10% difference in searcher efficiency for medium birds between components), we believe we have the power to detect reasonable differences between visibility categories should they exist. In addition, while stratification of visibility is a reasonable design parameter, the general high detection rates observed in the solar arrays and relatively small differences in detection greatly limit the potential influence this decision has on fatality estimates.
FWS21	Please explain the dots in the figure. The number of dots is greater than the number of trial carcasses.	The dots represent trial carcasses used for the estimation of searcher efficiency in the solar arrays, which includes trial carcasses

Agency Comment Number or Section-Line number reference	Agency Comment	Response from Desert Sunlight – reference new section
		from multiple seasons (supported by AIC modeling – see section 2.3.2). We revised the title for Table 5 to clarify: Estimated detection probabilities for bird carcasses by size class across all available seasons used for during summer (June 01 – August 30) 2015 fatality estimates at the Desert Sunlight Solar Farm Project, Riverside County, California.
FWS22	The denominator (w) from the equation for p (from page 12 equation) is missing from this equation. Is this a typo or was the equation modified for a reason? If so, please explain.	We have revised the typo in the equation.
FWS23	Please provide the values for n_{70} and n_{140}.	We have revised the text to include the values: where $n_{70} = 2580$ is the number of 70-m rows in the sample, $n_{140} = 4020$ is the number of 140-m rows in the sample, and *n* is the total number of rows in the sample.
FWS24	Is this the weighted average probability from above?	Yes. We inserted text to clarify: where *F* is the total number of fatalities, *C* is the number fatalities detected and included in fatality estimation, *r* is the probability a carcass is not scavenged and available to be found at the end of the search interval, and *p* is the probability of detecting a carcass (Huso 2010). Huso (2010) describes the use of a binomial model to estimate the probability of carcass detection; in the present study, the binomial carcass detection model was used to calculate fatalities at project linear features (fence, overhead lines), and the weighted average probability of detection based on distance sampling (described above) was used to estimate probability of detection within the solar arrays.

Agency Comment Number or Section-Line number reference	Agency Comment	Response from Desert Sunlight – reference new section
FWS25	Please describe what was bootstrapped and how. The table in the appendix is difficult to understand without a better understanding of the bootstrapping methods.	We revised the text in Section 2.4 to clarify: A total of 1,000 bootstrap replicates was used for each variable including searcher efficiency (*p*), probability of a carcass persisting to the next search ($\hat{r}$), adjusted search interval and observed fatalities. From these bootstrap samples, the probability of available and detected was calculated and applied to the bootstrapped observed fatalities.
FWS26	Aechmophorus species or a different genus?	Yes, *Aechmophorus* sp. Revised.
FWS27	Was proximity to project features evaluated? Please describe how this information was utilized. Proximity distances may provide insights into which features may pose the greatest risks.	These data are reported in the monthly Avian Injury & Mortality Report. These data will be reported in the annual report but are beyond the scope and schedule of seasonal reports. We have included maps of the fatality locations to help understand any large scale patterns and we will be presenting additional maps by guild in the annual report. During the January TAG meeting, we presented such maps.
FWS28	Since scavenger rates are so high, this definition too easily categorizes carcasses as unknown. Low levels of scavenging should not exclude birds from a more thoughtful evaluation of the cause of the mortality. Other criteria should be considered, including patterns of disturbed dust on solar panels, proximity to a feature with collision risk. Such a blanket categorization, probably masks useful information.	Other criteria are considered. We revised text in section 2.1.2 and the footnote of Table 5 to clarify: Suspected cause of death or injury was assigned based on evidence available from the detection, evidence available on Project infrastructure, and proximity of the detection to Project infrastructure. Detections that had evidence of scavenging and lacked evidence on Project infrastructure were assigned as “unknown” because it cannot be determined whether the event was caused by predation or interaction with project infrastructure.

Agency Comment Number or Section-Line number reference	Agency Comment	Response from Desert Sunlight – reference new section
		Assignments to “suspected cause of death” categories reported in the DSL spring 2015 post-construction monitoring report is consistent with what has been reported in previously-submitted monthly SPUT reports. Per recent discussions, we are looking for additional guidance provided with the SPUT report on making determinations of suspected cause of death. In addition, we will be presenting statistics in the final report such as the percent of fresh carcasses that showed collision evidence (e.g. broken neck, beak damage). We also are interested in understanding what the USFWS plans for the carcasses in the freezers, and whether they plan to necropsy those birds.
FWS29	Spatial distribution of different taxonomic groups should be discussed, particularly as more data come in.	Spatial distribution of carcasses is reported in Table 2. To include discussion of this topic at present would not be meaningful, and it will be addressed in the annual report. We presented maps of spatial distribution for waterfowl/waterbirds during the January TAG meeting.
FWS30	This is not clear. Are you suggesting that feather spots from large carcasses last longer than feather spots from small carcasses? Or are you suggesting that large carcasses are more likely to produce feather spots than small carcasses and feather spots in general (large or small) persist for long durations? Please clarify and provide a rationale for the assertion and describe how it might affect the analysis.	We have removed reference to feather spots and revised the text in Section 3.6 to clarify: Carcass size was tested as a potentially important variable, as larger carcasses tend to persist longer than smaller carcasses.
FWS31	Is there enough data to do a good analysis?	The approved Desert Sunlight BBCS states that the goal is to gain a general

Agency Comment Number or Section-Line number reference	Agency Comment	Response from Desert Sunlight – reference new section
		understanding of the magnitude of the impacts of the solar facility, not necessarily a highly precise estimate of fatalities. The study has been designed to meet that objective. Additional analyses will be conducted for the annual report, after a year of data is available as well as on-going through the 2nd year of monitoring. These additional data will result in increased power to detect patterns, and likely increased precision of point estimates.
FWS32	Please include the timeframe for the persistence trials for ease of reference (30 days?).	The persistence probabilities presented in Table 6 represent the probability of a carcass persisting through the effective search interval. Thus, the 30-day timeframe for the trial is irrelevant to the results presented in the table. We added the effective search interval to the table title for ease of reference.
FWS33	This looks like there may be an effect on persistence time from being outside the fence. This may be due to differences in the scavenger community. Was this tested?	We did not test the scavenger community, but we did test the hypothesis that carcass persistence time inside the fence was different than persistence time outside the fence by comparing models of carcass persistence with and without a covariate for project component using an information-theoretic framework. The best model supported the hypothesis that persistence times were specific to project component, hence we reported two different estimates of persistence. We have revised text in section 3.6 to clarify: The model with lowest AICc score is typically chosen as the “best” model relative to other models tested; however, any model within two AICc points of the best model is

Agency Comment Number or Section-Line number reference	Agency Comment	Response from Desert Sunlight – reference new section
		considered competitive with the best model (Burnham and Anderson 2004). The best model had a ∆AICc value of 0.77 and included effects of carcass size (small, medium or large), and location (solar arrays/fence or generation-tie line) with a Weibull-distributed removal time, but no effect of season. Estimates of carcass removal time and persistence probabilities are reported from the best model in Table 6.
FWS34	This is the Gen-Tie, right? Better to refer to this as the Gen-Tie to distinguish it from the internal overhead lines above the panels.	Revision accepted.
FWS35	The y-axis is cut off at 0.5. This obscures data for small and med bird size categories. Please provide the Figure with a y-axis range from 0.0-1.0.	We have revised Figure 7 to correct the Y-axis.
FWS36	How was this broken down by visibility categories and size classes? See Appendix C?	A breakdown of sample sizes for searcher efficiency trials is found in section 2.3.1. WEST will report more detailed results regarding how many were available to be found by category in the annual report. This level of detail is beyond the scope and schedule of the seasonal reports.
FWS37	Please provide an additional summary table with the following information for each component and for the entire facility: carcasses detected, estimated fatalities; 90% CI. An additional table with the same information for each size category is also requested.	All of the requested information is presented in Appendix C. We revised the text to direct readers to Appendix C.: Detections used in the analysis, bias corrections, summer fatality estimates, and 90% confidence intervals for summer fatality estimates are detailed in Appendix C.
FWS38	The Service continues to recommend 95% CI, but even at 90% the CI is still too wide to be useful.	90% confidence intervals are the standard in renewable energy and many field studies (Arnett 2005; TRC Environmental Corporation 2008; Johnson et al. 2009). There are other intervals used as well, often

Agency Comment Number or Section-Line number reference	Agency Comment	Response from Desert Sunlight – reference new section
		wider than 90%, including the USFWS use of 80% credible intervals for the Eagle Risk Model and 50% credible interval is being considered in some regional Habitat Conservation Plans. Study examples of the use of 90% confidence intervals include the USFWS Western-wide eagle surveys (Nielson et al 2014) as well as the WAFWA prairie chicken surveys (McDonald et al. 2015)
FWS39	Given the size of utility scale projects "per 1000 acres" seems more appropriate.	Revision accepted but we believe a per acre basis is also relevant because other studies that may serve as comparisons are reported on a per acre basis. We reported it both ways.
FWS40	Given the low number of trial carcasses, you can detect a difference between visibility classes [sic].	We have revised the text in Section 4.1 to clarify: Placement of trial carcasses in both difficult and easy visibility classes ensures that the adjustment due to searcher efficiency accounts for both visibility classes, even if there is a real difference in searcher efficiency that cannot be detected with the trial data.
FWS41	What fraction of these unknown detections are feather spots?	We revised text in Section 4.2 to include the percentage of feather spots that made up "unknown cause" detections.
FWS42	We don't agree with this statement. This is unknown. Feather spots may be more mobile, but as far as I know there have been no studies on whether they "multiply" and cause bias. If there has, please provide a reference. It is possible that feather spots could accumulate along fences, but in general, they are just as likely to migrate into a survey area as they are to leave. If	We inserted text to clarify: Further, game cameras trained on carcasses for carcass persistence trials at the Project have documented multiple feather spots originating from a single trial carcass. Ravens and turkey vultures, and possibly roadrunners, dislodge feathers from their attachment to the skin of carcasses during the scavenging process. There are a very

Agency Comment Number or Section-Line number reference	Agency Comment	Response from Desert Sunlight – reference new section
	this is a significant problem, then I recommend shorter search intervals and more complete coverage of the project site.	large number of potential feather spots present on a single bird carcass (because a feather spot is defined as at least two or more primary flight feathers, at least five or more tail feathers, or two primaries within five m (16.4 ft) or less of each other, or a total of 10 or more feathers of any type concentrated together in an area of three square m).
FWS43	This table/appendix requires more explanation.	We have revised the table title and added more descriptive section titles for clarification.
Additional revisions		
NA		We added two tables to the report (Table 7 in Section 3.8 and Table C-2 in Appendix C) to clarify which carcasses were excluded from the fatality analysis. We also revised the maps to reflect carcass status in the fatality analysis.

Draft Pre-Decisional Document – Privileged and Confidential – Not For Distribution

EXECUTIVE SUMMARY

Avian and bat monitoring surveys were conducted from March 1, 2015 to February 28, 2016 (the 2015 – 2016 monitoring year) at Desert Sunlight Solar Farm Project (Project) in accordance with the Project's Bird and Bat Conservation Strategy (BBCS). Specifically, standardized carcass searches, searcher efficiency trials, and carcass persistence trials were conducted. This report represents the comprehensive annual report for the first year of monitoring, and summarizes monitoring methods and results for those surveys based on the procedures and requirements specified in the BBCS.

Standardized carcass searches were conducted 1) in the solar field, consisting of a random stratified 29.5% sample of solar photovoltaic (PV) panels, 2) along inner portions of the fenceline, resulting in 74.4% of the length of the perimeter fence, and 3) along 47.9% of the total length of generation-tie (gen-tie) line from the Project fence to the Red Bluff Substation located south of Interstate 10 (I-10). Searches were conducted at intervals of approximately seven days during spring and fall and 21 days during summer and winter.

All bird and bat fatalities and injuries that were discovered by observers, referred to as "detections" in this report, including those found incidentally and during standardized carcass searches, were documented. During the reporting period, 149 avian detections (including all stranded and injured birds and incidental detections), of 19 guilds and including 53 identified species, were made. The most numerous detection of an identified species was of American coot (*Fulica americana*) with 12 detections, followed by mourning dove (*Zenaida macroura*; n = 6). The most numerous detection in the solar arrays was American coot (n = 9), followed by western grebe (*Aechmophorus occidentalis*; n = 5) with no other species with more than four detections. The only species observed along the fence were American coot (n = 1), common raven (*Corvus corax*; n = 1), common loon (*Gavia immer*; n = 1), white-winged dove (*Zenaida asiatica*; n = 1), and mallard (*Anas platyrhynchos*; n = 1). Eurasian collared-dove (*Streptopelia decaocto*; n = 4) and orange-crowned warbler (*Oreothlypis celata*; n = 3) were the species with the most detections along the gen-tie/road. No bats were detected during the 2015 – 2016 monitoring year.

Avian detections were categorized by likely diurnal or nocturnal migration behavior, ecological guild (e.g., raptors, songbirds, etc.), facility component, and suspected cause of death. These standardized carcass search results, along with searcher efficiency and carcass persistence rates from bias trials conducted on site, were applied to a fatality estimator model (Huso 2010) to provide an estimate of the number of fatalities that occurred at the Project during the reporting period adjusted for sources of bias.

Mean (median) removal time within the solar field was 4.9 (6.0) days during spring, 12.7 (12.6) during summer, 2.5 (1.5) during fall, and 6.5 (6.0) during winter for small carcasses; 36.0 (27.8) days during spring, 36.0 (24.3) during summer, 12.2 (18.0) during fall, and 12.2 (6.8) during winter for medium carcasses; and 58.3 (31.0) days during spring, 13.7 (30.0) during summer,

58.3 (30.0) during fall, and 13.7 (5.1) during winter. At the overhead lines, removal time was 0.8 (0.5), 0.8 (0.5), 0.4 (0.5), and 2.3 (2.5) during spring, summer, fall, and winter respectively. For medium birds, mean (median) removal time at the overhead lines was 14.4 (2.0), 14.4 (15.8), 4.9 (1.5), and 4.9 (2.5) days during spring, summer, fall, and winter respectively. Mean (median) removal time for large birds was 5.8 (19.0), 1.4 (0.5), 5.8 (3.5), and 1.4 (3.5) days during spring, summer, fall, and winter respectively.

Within the solar arrays, searcher efficiency for small birds was influenced by cobble cover and season: small birds in high cobble cover in the fall had a searcher efficiency of 33.2% (CI: 13.3 – 63.9%; n = 15) and small birds in low cobble cover in the fall had a searcher efficiency of 57.8% (CI: 39.0 – 77.7%; n = 27). Searcher efficiency for small birds in high cobble cover during winter, spring and summer was 36.0% (CI: 21.1 – 45.4%; n = 50), and small birds in low cobble cover during winter, spring and summer had a searcher efficiency of 64.5% (CI: 44.5 – 63.4%; n = 70). For medium birds, searcher efficiency within the solar arrays was similar across cobble cover classes but differed by season: in winter, medium bird searcher efficiency was 93.5% (CI: 87.5 – 98.5%; n = 45), and in spring, summer and fall medium bird searcher efficiency was 83.2% (CI: 76.5 – 89.8%; n = 63). For large birds, searcher efficiency among the solar arrays differed between migration seasons (spring and fall) and non-migration seasons (summer and winter). Searcher efficiency during spring and fall for large birds was 83.9% (CI: 72.0 – 94.3%; n = 31). Searcher efficiency for large birds during summer and winter was 100% with no variance (n = 35). Sample sizes refer to numbers of trial carcasses that were available to be found, not numbers of trial carcasses that were placed.

For the fence, the model that included an effect of carcass size, and season (with spring and winter data lumped and summer and fall data lumped) was chosen as the most supported model to estimate searcher efficiency. Along the fence, searcher efficiency was 65% (CI: 52 – 77%), 94% (CI: 88 - 100%), and 100% (CI: 100 - 100%), for small, medium, and large carcasses, respectively during spring and winter and 87% (CI: 77 – 97%), 98% (CI: 96 – 100%), and 100% (CI: 100 – 100%) for small, medium, and large carcasses respectively during summer and fall.

For the gen-tie line, the chosen model included main effects of size, season (with spring and summer data lumped and fall and winter data lumped), and visibility class, with an interaction between visibility class and season. It ranked second by AICc, but was only 0.59 AICc points from the top model. It was chosen because it has similar predictive performance as the top model, but with fewer parameters to estimate. For the easy visibility class, searcher efficiency was 67% (CI: 53 – 81%), 89% (CI: 80 – 95%), and 89% (CI: 80 – 96%) for small, medium, and large carcasses, respectively during spring and summer and 57% (CI:46 – 68%), 84% (CI: 75 – 91%), and 85% (CI: 73 – 93%) for small, medium, and large birds respectively during fall and winter (Table 12). For the difficult visibility class, searcher efficiency was 75% (CI: 62 – 86%), 92% (CI: 86 – 97%), and 92% (CI: 84 – 97%) for small, medium, and large birds respectively during spring and summer and 33% (CI: 22 – 44%), 65% (CI: 53 – 77%), and 67% (CI: 51 – 82 %) for small, medium, and large birds respectively during fall and winter.

Using the Huso (2010) fatality estimator model, during the 2015 – 2016 monitoring year, there were an estimated 1,328 bird carcasses (CI: 1,007 – 2,303) at the Project (all components combined). There were an estimated 53 (CI: 28 – 85) large birds, 336 (CI: 246 – 449) medium birds, 881 (CI: 566 – 1,843) small birds, and 58 (CI: 22 – 143) birds of unknown size at the Project (all components combined).

There were an estimated 628 (CI: 496 – 951) bird carcasses (152/1000 acres, 1.16/nameplateMW) at the solar arrays, 11 (CI: 2 – 26) at the fence, and 688 (CI: 364 – 1,567) along the gen-tie line. Estimates of fatalities along the gen-tie are heavily influenced by the high rates of scavenging observed during the limited trials at the gen-tie (i.e., large correction factors) and are likely very unreliable.

1 INTRODUCTION

1.1 Project Background

Desert Sunlight 250, LLC and Desert Sunlight 300, LLC (collectively, Desert Sunlight) constructed and operates the Desert Sunlight Solar Farm Project (Project), which consists of two main components: 1) a 550-megawatt (MW) photovoltaic (PV) generating facility; and 2) a 220-kilovolt generation interconnection (gen-tie) line. The Project comprises approximately 1,700 hectares (ha; 4,200 acres) of land administered by the Bureau of Land Management (BLM) six miles north of Desert Center in Riverside County, California (Figure 1).

1.2 Monitoring Plan Overview and Goals

A Bird and Bat Conservation Strategy (BBCS; 2014) was prepared by the Project proponent in collaboration with the US Fish and Wildlife Service (USFWS), California Department of Fish and Wildlife (CDFW), and BLM to guide comprehensive monitoring of impacts to birds and bats associated with operation of the Project. Final agency approval of the BBCS occurred in December 2014. Amendments to the sampling protocol along some portions of the Project fenceline were made by Desert Sunlight and approved by the BLM on February 11, 2015.

The BBCS details post-construction monitoring to be conducted and the data analysis and reporting processes that will be implemented by Desert Sunlight in collaboration with the USFWS, CDFW, and BLM. As identified in the BBCS, they are:

1. Estimate overall annual avian fatality rate and species composition associated with the Project infrastructure. This estimate will include mortality associated with solar arrays, overhead lines including the gen-tie line, perimeter fence and other features of the Project that may result in injury and fatality.

2. Determine whether there are spatial and temporal/seasonal patterns of mortality associated with Project infrastructure (e.g., different fatality rates near panels on the edge of the arrays vs. the interior area of the arrays).
3. Provide information that will assist the BLM in consultation with the USFWS in understanding which species and potentially which regional populations are at risk.
4. Collect data in such a way that the BLM in consultation with the USFWS may make comparisons with other solar sites.

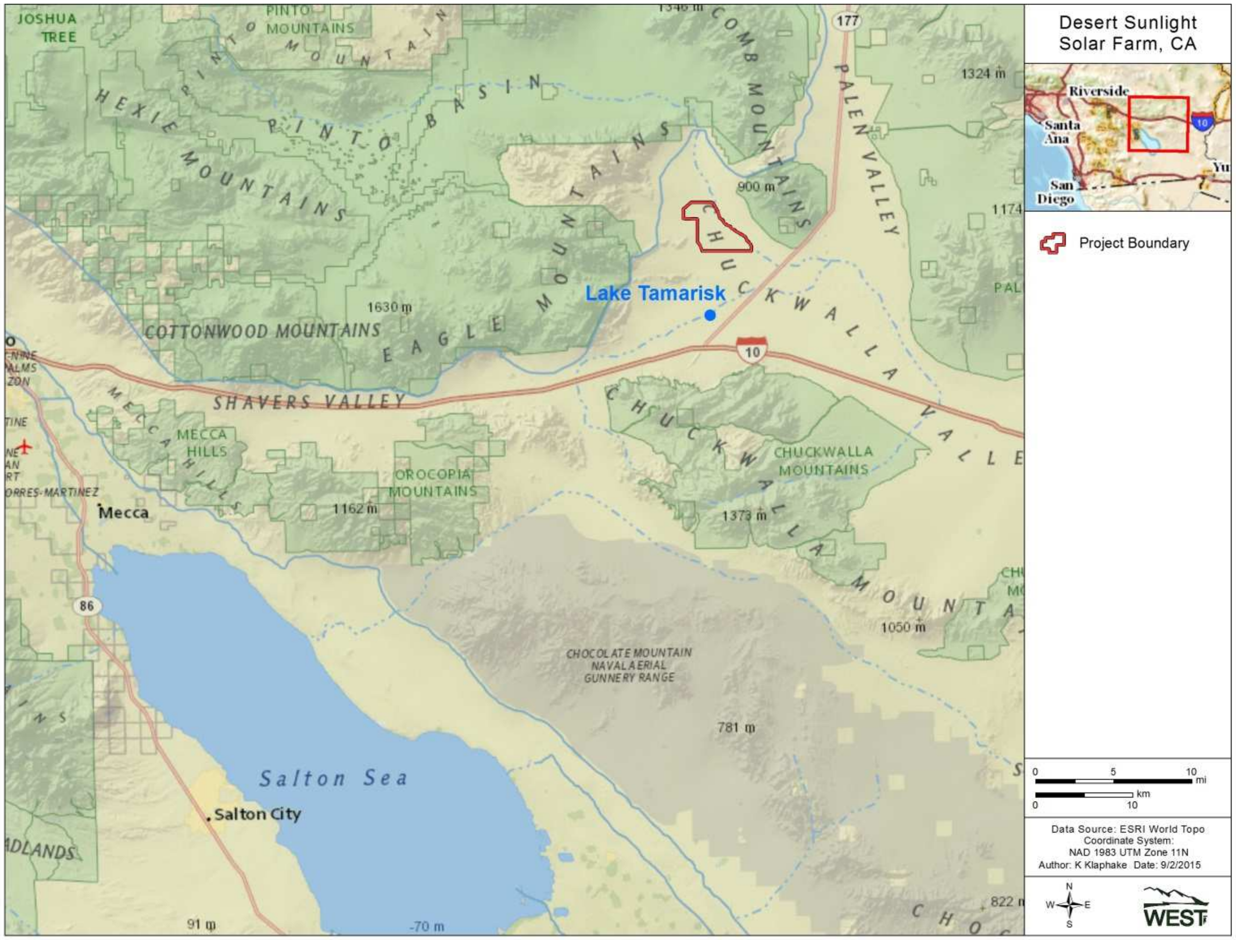

Figure 1. Desert Sunlight Solar Farm Project vicinity map, Riverside County, California.

1.3 Purpose of This Report

This report represents the comprehensive annual report for the first year of monitoring summarizing monitoring methods and results for avian and bat fatalities and injuries based on the procedures and requirements specified in the approved BBCS. This report includes data and final information from all four quarterly monitoring periods.

This report covers the 2015 – 2016 monitoring year, which includes the period from March 1, 2015 to February 28, 2016. All carcasses and injuries that were discovered by observers are referred to as “detections” in this report. As stated in the approved BBCS, this report includes the observed detections for likely diurnal, and likely nocturnal species, and for ecological guilds of interest (e.g., raptors, water-associated birds, passerines), for each of the facility types and for suspected causes of death. Species composition of detections and the results of the bias trials are also included in this report.

2 METHODS

The following section describes the field and statistical methods used during the monitoring period, including the analytical methods for estimating overall avian fatality rates.

2.1 Standardized Carcass Searches

This section describes areas surveyed, the timing and frequency of searches, and the methods by which standardized searches were conducted to identify dead/injured birds and bats at the Project. This section also describes the methods for conducting carcass removal and searcher efficiency trials; the methods for reporting and analyzing data, and the methods for producing fatality estimates for the Project.

2.1.1 Areas Surveyed

Standardized carcass searches were conducted at sampling units, which include the solar arrays (Table 1, 2; Figure 2); the “fenceline” defined as the perimeter fence for the Project (Table 1, Figure 2); and the gen-tie line (from the Project fence to the Red Bluff Substation on the south side of I-10; Table 1, Figure 3). Some overhead lines co-occur with solar arrays (medium voltage overhead (MVOH) lines). The MVOH lines were part of standardized carcass searches to the extent that they co-occurred with solar arrays included in the sample (Table 2; Figure 2).

Table 1. Areas included in standardized carcass searches at the Desert Sunlight Solar Farm Project during the 2015 – 2016 monitoring year (March 1, 2015 – February 28, 2016).

Project Component	Total Size	Units	% of Component Searched
Solar arrays	1045.9	Hectares	30.0[1]
Fence	16.7	Kilometers	99.0[2]
Gen-tie line	19.2	Kilometers	47.9[3]

[1] Percent area that was searched in spring (28.2) summer (29.5), fall (29.5), and winter (29.5), slightly less than 30% total because of unequally sized arrays.

[2] 74.4% of the fence is fully accessible and surveyed following the standard protocol, while approximately 25% of the fence is surveyed from a distance. Fatality rates estimated for sections of the fence that are sampled were extrapolated to sections of the fence where the standard monitoring protocol cannot be used, as described in Section 4.2.6 of the approved Desert Sunlight BBCS. A very short segment near the gate is not sampled due to restoration activities.

[3] 52.1% of the gen-tie will be sampled in 2016.

Comentado [A1]: Is this supposed to be 99.4 based on the footnote explanation?

Table 2. Area and proportion of solar arrays that are and are not associated with overhead lines at the Desert Sunlight Solar Farm Project, Riverside County, CA.

	Line-associated[1]	Not line-associated	Proportion line-associated
Entire facility	89.4 ha	956.5 ha	0.09
Standardized searches	32.2 ha	291.0 ha	0.10

[1] Line-associated area was estimated as the area of any array that fell within the 30-m strip transect below the MVOH line.

Note: Hectares (ha)

To ensure a balanced distribution of sample units in the solar field (defined as the collection of all PV solar panels), the entire field was divided into ten strata, and individual sampling units were randomly selected within each stratum to compose an approximately 30% sample. This sampling design ensures that units included in the sample were not spatially clumped within the solar field. The solar field consists of arrays of solar panels (referred to as a solar array) that are either 70 meters (m) or 140-m wide. The sample includes 133 of each type of array. There are 2,580 70-m rows, and 3,900 140-m rows in the sample.

On April 21, 2015, the Project was struck by a tornado. The tornado damaged some of the sampling units and resulted in limited access that ultimately lasted longer than initially expected. Thus, 142 sample units (128 arrays, fence, and gen-tie combined) were visited 12 times continuously and without interruption during the spring season. Six arrays were visited seven times from the beginning of the spring season until the tornado occurred on April 21, 2015; three weeks elapsed before the six damaged arrays were replaced with arrays in the solar field that were not affected by the tornado. During this three week period, Desert Sunlight LLC remained in contact with the BLM as details on access limitation developed. Once it was determined that access to damaged arrays would be limited for a longer time period, six replacement arrays were identified by choosing a random sample of non-damaged arrays within the same block that contained the original arrays that were damaged by the tornado.

2.1.2 Search Frequency and Timing

Standardized searches occurred during the 2015 – 2016 monitoring year, which includes the period from March 1, 2015 through February 28, 2016. All Project components included in standardized searches were surveyed 31 times during the 2015 – 2016 monitoring year (12 times during spring, four times during summer, nine times during fall, and six times during winter). All searches took place during daylight hours from 06:30 to 17:00.

The average search interval for all Project components included in standardized carcass searches was 7.0 (median 7.0) during spring, 22.8 days (median 21.0 days) during summer, 8.1 days (median 7.0 days) during fall, and 19.1 days (median 21.0 days) during winter. Slight variation in search interval was anticipated due to weather and logistical delays.

2.1.3 Search Methods

Standardized carcass searches were performed by BLM-approved biologists in accordance with methods outlined in the BBCS.

Within the solar field, arrays of solar panels were surveyed by observers traveling on foot. A distance sampling approach was used whereby biologists slowly walked a transect line along the ends of rows of solar panels in a direction perpendicular to the rows, searching ahead and to the side within the array for bird and bat detections. Biologists scanned out to a maximum perpendicular distance of approximately 70 m from the transect. Biologists carried binoculars to allow them to verify the presence of a detection as opposed to rocks or vegetation. Once a detection was confirmed, the distance of the detection to the transect line was estimated using laser range finders. Each array included in the sample was searched by observers walking two transects – one on the west side and one on the east side of the array with observers looking toward the center of the array.

Comentado [A2]: Does the observer stop and scan with binoculars at each row? Or do they just walk slowly look with the naked eye and then use binocs if they see something? They walk slowly use the naked eye and stop only if they see something.

Once a carcass was detected, it was photographed, and data were recorded according to specifications outlined in Section 7.2.5 of the approved Desert Sunlight BBCS. Carcasses were then retrieved from their location on the ground, labeled, and placed in a freezer on site.

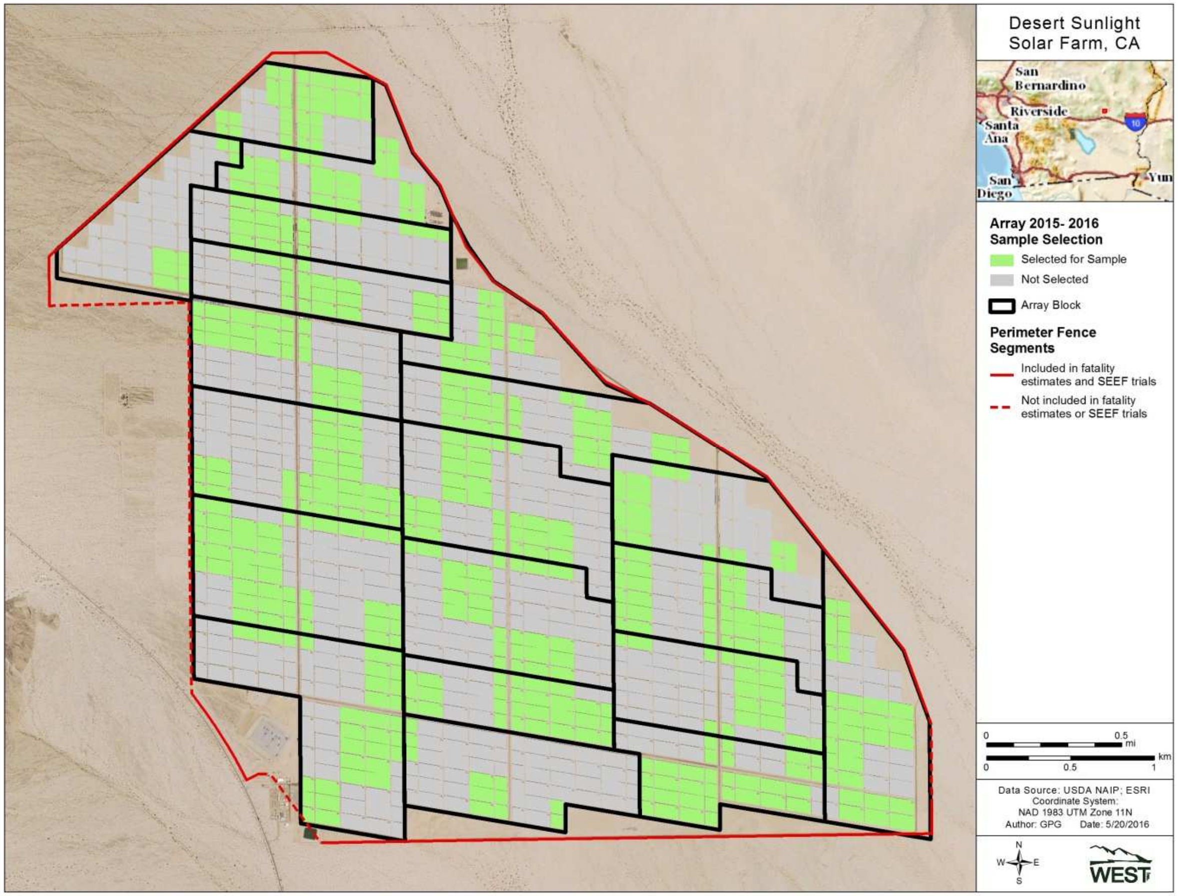

Figure 2. Areas of standardized searches at the solar field, visitor center, and overhead lines within the fence at Desert Sunlight Solar Farm Project during the 2015 – 2016 monitoring year (March 1, 2015 – February 28, 2016).

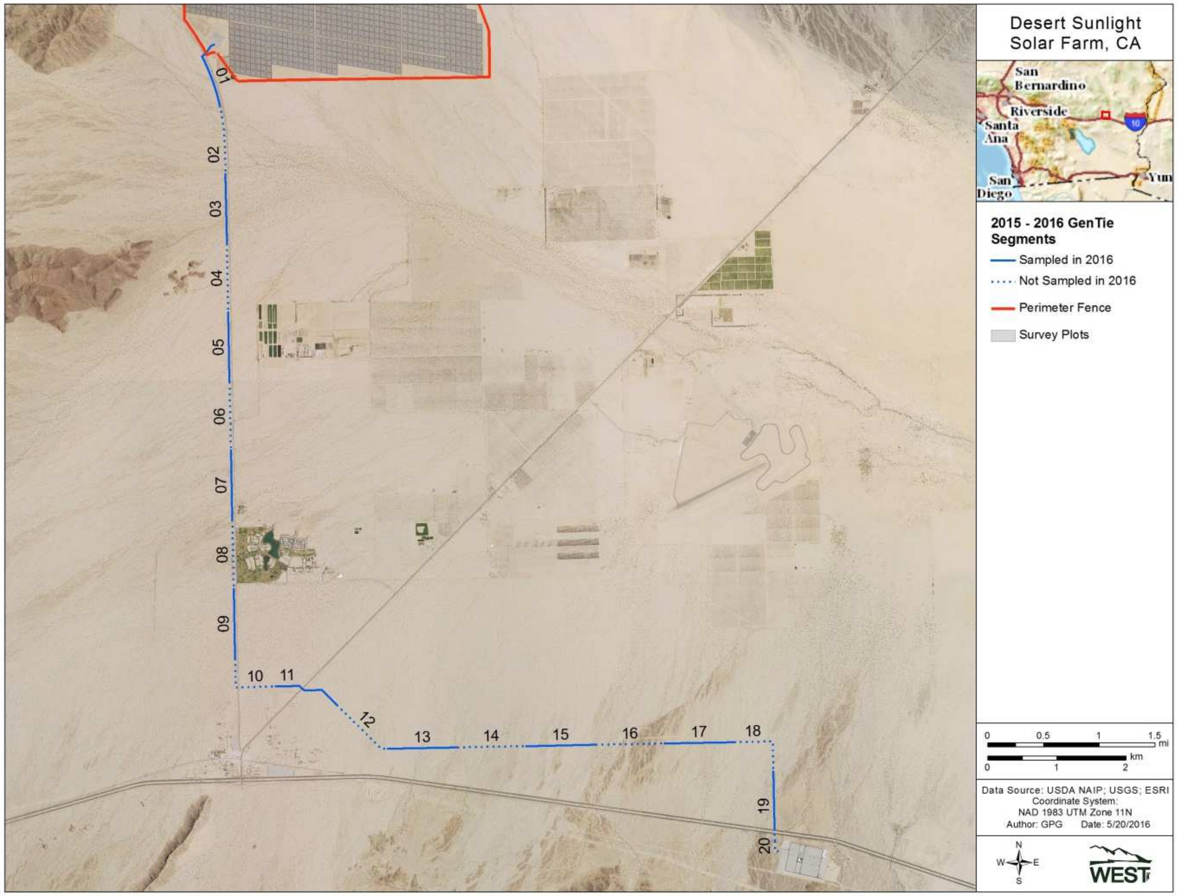

Figure 3. Areas of standardized searches along the generation tie line at Desert Sunlight Solar Farm Project during the 2015 – 2016 monitoring year (March 1, 2015 – February 28, 2016).

Most (74.4%) of the length of fenceline (approximately 10 miles; Figure 2) was searched from a vehicle using the standard protocol. Biologists searched a 6-m wide strip transect centered on the fence from the inner perimeter. Travel speed was below five miles per hour (mph) while searching. Some sections along the fence cannot be driven close to the fence line. The fence line along the western edge of the Project is drivable but the road is approximately 15 m away from the fence and the road and fence are separated by a drainage ditch. The fence along this section is covered with a tan tarp and trees and shrubs have been planted to reduce visibility of the Project from the west. Additions of vegetation and the tarp likely reduce potential for bird collision with the fence. This section of the fence was driven to document carcasses, but detections along this portion of the fence are not included in adjusted fatality estimates because detection rates are likely very low. As specified in Section 4.2.6 in the approved Desert Sunlight BBCS, we assume that fatality rates are similar between the portion of fence that was searched and the portion that was not. A separate section of the fence in the southeastern corner of the Project cannot be driven because the eastern edge of the berm that bounded construction ponds is too narrow for a vehicle. Along this portion of the fence, the observer stopped at both north and south ends of the berm and used binoculars to search for carcasses. Finally, the area along a portion of the southwest fence line near the entrance gate is approximately 30 to 50 m from the road and is separated from the fence by an area that has recently undergone vegetation restoration. This area was also eliminated from sampling. Fatality rates estimated for sections of the fence that were sampled were adjusted to account for the proportion of fence not sampled with the standard monitoring protocol, as specified in section 4.2.6 of the approved Desert Sunlight BBCS. In other words, the fatality rates (number of carcasses/m of fenceline sampled) was multiplied by the total fenceline in the facility to get the total fenceline carcass estimate for the facility.

The gen-tie line was searched using a 30-m wide strip transect (i.e., 15 m of ground on either side of the overhead line). Sample units along the gen-tie line were chosen by dividing the total length of line from the Project fence south to the Red Bluff Substation just south of I-10 into 1-kilometer (km) segments. Thus, a 47.9% sample of the total length of the line was searched (Figure 3). Biologists slowly walked every other 1-km segment of the line, meandering the width of the strip transect, scanning for dead or injured birds or bats within 15 m (49.2 feet [ft]) of the overhead line.

For each detection, a suspected cause of death or injury was assigned based on evidence available from the detection, evidence available on Project infrastructure, and proximity of the detection to Project infrastructure. Detections that had evidence of scavenging and lacked evidence on Project infrastructure were assigned “unknown” cause of death because it cannot be determined whether the event was caused by predation or interaction with Project infrastructure. Detections that were intact (i.e., no evidence of scavenging) and located in close proximity to Project infrastructure (e.g., found directly beneath overhead lines) had a suspected cause of death attributed to the respective Project component. However, it should be noted that there is substantial uncertainty associated with cause of death assignments because no events were directly observed. Detections assigned to the “unknown” category were included in fatality estimates if they were located within standardized carcass search areas, and all detections made during the 2015 – 2016 monitoring year are reported here.

2.2 Carcass Persistence Trials

Carcass persistence trials were conducted in each of the four seasons during the 2015 – 2016 monitoring year. Carcasses from three size classes were used for trials (small: zero-100 grams [g], medium: 101-999 g, and large: 1000+ g). The small size class comprised house sparrows (*Passer domesticus*) and 2-3 week old coturnix quails (*Coturnix coturnix*), the medium size class comprised rock pigeons (*Columba livia*), chukar (*Alectoris chukar*) and adult coturnix quail, and the large size class comprised of hen mallards (*Anas platyrhynchos*) and hen ring-necked pheasants (*Phasianus colchicus*).

2.2.1 Carcass Persistence Data Collection

To quantify carcass persistence rates, 15 small, 10 medium, and 5 large carcasses were randomly placed and monitored along the gen-tie line during each seasonal monitoring period. Within the solar arrays the same numbers of each size category were placed at Desert Sunlight, as specified in the approved Desert Sunlight BBCS. During spring, an additional five large bird carcasses were placed within the solar arrays. During winter, an additional five large birds (two along the gen-tie and three within the solar arrays), 10 medium birds (five along the gen-tie and five within the solar arrays), and 15 small birds (eight along the gen-tie and seven within the solar arrays) were placed. Thus, 275 carcasses were placed during the 2015 – 2016 monitoring year. By placing carcasses inside (within arrays and along inner perimeter of the fence) and outside (along the gen-tie) the Project fence, the possibility of different carcass persistence rates inside and outside the Project fence is accounted for. During the 2015 – 2016 monitoring year, 70 carcasses (13 during spring, 15 during summer, 15 during fall, and 27 during winter) within the Project fence (within solar arrays and along the fence) were monitored using motion-triggered digital trail cameras as well as by visits on foot. The remaining carcasses were visited on foot for 30 days or until the carcass had deteriorated to a condition at which it would no longer qualify as a documentable fatality. No carcasses along the gen-tie line were monitored with cameras because of theft and vandalism concerns. Carcasses without trail cameras were visited and photographed once per day for the first four days, and then every three to five days until the end of the monitoring period. To avoid training scavengers to recognize cameras as "feeding stations," trail cameras were installed five days before specimens were placed. In addition, two fake cameras (four cameras used during spring) were placed within the Project fence in areas without bias trial carcasses and periodically moved to new locations within the fence. Periodic ground-based checking of carcasses with trail cameras also occurred to guard against misleading indicators of carcass removal, such as wind blowing the carcass out of the camera's field of view. To minimize potential bias caused by scavenger swamping (Smallwood 2007, Smallwood et al. 2010), carcass-persistence specimens were distributed across the entire Project, not just in areas subject to standard searches, and trials were initiated in smaller numbers on two to three different dates throughout each of the four seasonal monitoring periods.

2.2.2 Estimating Carcass Persistence Times

Measurements of carcass persistence rates were subject to censoring. In this context, censoring refers to the instance when a value (e.g., days a carcass is present before being removed) may not be exactly known, but is known to be within a finite range. For example, suppose a carcass was checked on day seven and was present, and was checked again on day ten, but was found to be missing. The exact time until removal is unknown; however, it is known that the carcass became unavailable at some point between seven and ten days. This carcass would be considered “interval censored”. Similarly, if a carcass lasts the entire 30-day trial period, that carcass is “right censored”— it is known that the carcass lasted at least 30 days, but it may have persisted longer. Because carcass persistence data was censored, persistence was analyzed using methods that can accommodate censored data and still produce unbiased estimates of the probability of persistence (Therneau 2015, Therneau and Grambsch 2000). It is beyond the scope of this document to provide statistical foundations of censored-data survival models, but functions identical to those provided with the USGS-developed fatality estimator software (Huso et al 2012) were used to fit survival models to the censored carcass persistence data, and some background is available in the documentation provided with that software.

USGS-developed fatality estimator software (Huso et al 2012) was used to fit survival models to the censored carcass persistence data. The USGS software used to estimate carcass persistence calculates the period over which there is less than a 1% chance for a carcass to persist. The 'effective search interval' is defined as the shorter of a) the length of time beyond which there is less than a 1% probability that a carcass persists, and b) the actual search interval (Huso 2010). The probability of persistence is given for the effective search interval, and the probability that a carcass persists through the actual search interval is equal to *p* (persist through effective search interval) * effective search interval / actual search interval.

There were four distributions implemented in survival models used to estimate the probability a carcass is un-scavenged and available to be found at the end of the search interval (*r*): exponential, Weibull, loglogistic, and lognormal. These four distributions exhibit varying degrees of flexibility in order to model a wide variety of distributions of persistence time. Akaike’s Information Criterion corrected for sample size (AICc; Akaike 1973) was used to rank the fit of each survival model with combinations of the covariates carcass size, Project component, season, and visibility, to observed carcass persistence data.

2.3 Searcher Efficiency Trials

Searcher efficiency trials were conducted throughout the 2015 – 2016 monitoring year. Carcasses from three size classes (small, medium, and large) were used for trials. The small size class comprised house sparrows and two- to three-week-old coturnix quails, the medium size class comprised rock pigeons, chukars, and older coturnix quails, and the large size class comprised hen mallards and hen ring-necked pheasants.

2.3.1 Searcher Efficiency Data Collection

Training of biologists on the Project-specific protocol and early assessments of habitat conditions within the solar arrays suggested that the amount of cobble present in the soil may be an important factor influencing searcher efficiency. To satisfy requirements regarding consideration of visibility class per the BBCS and address the influence of cobble cover on searcher efficiency, sample units in the solar arrays and along the gen-tie were stratified by cobble cover and assigned to one of two classes (<15% and >15% cobble cover). Classes were determined by making ocular estimates of cobble cover at each sample unit and then evaluating the frequency histogram of sample units across the range of estimated cobble cover (Figure 4). A natural break point was identified at 15% cobble cover, so the same value was chosen as the break point that defined the two cobble cover classes. The high cobble class made up only 13% of the sample units. Thus, in the solar arrays, two sets of searcher efficiency trials were conducted during the 2015 – 2016 monitoring year (one set in each cobble cover class; *n* in low cobble equals 110 small birds, 71 medium birds, and 41 large birds; *n* in high cobble equals 71 small birds, 42 medium birds and 25 large birds [see Table 3 for placement by size, visibility class, and Project component for each season]). Along the gen-tie, visibility was expected to be related to vegetation and rock cover. Thus, searcher efficiency trials along the gen-tie occurred in two visibility classes (easy: ≥90% bare ground, vegetation <6" tall; and more difficult: <90% bare ground, vegetation ≥6" tall). Sample sizes for the easy class and the more difficult class were 75 small birds, 50 medium birds, and 27 large birds and 76 small birds, 50 medium birds, and 27 large birds respectively. The entire fence line was considered an easy visibility class. One hundred fifty searcher efficiency trials occurred along the fence (n = 75 small birds, 50 medium birds, 25 large birds). During the 2015 – 2016 monitoring year, 810 searcher efficiency trials occurred at the Project. Locations for trials were chosen by taking a randomized sample of all locations included in standardized carcass searches.

Table 3. Searcher Efficiency Placements by size, visibility class, and Project component for each of the four seasonal monitoring periods at the Desert Sunlight Solar Farm Project, Riverside County, California.

Project Component	Visibility Class	Size	Spring	Summer	Fall	Winter	Total
Solar Arrays	High	LB	4	0	6	15	25
Solar Arrays	High	MB	3	0	9	30	42
Solar Arrays	High	SB	11	0	15	45	71
Solar Arrays	Low	LB	12	10	9	10	41
Solar Arrays	Low	MB	10	20	21	20	71
Solar Arrays	Low	SB	20	30	30	30	110
Fence	Easy	LB	5	5	5	10	25
Fence	Easy	MB	10	10	10	20	50
Fence	Easy	SB	15	15	15	30	75
Gen-tie	Diff	LB	5	3	4	10	22
Gen-tie	Diff	MB	9	11	11	19	50
Gen-tie	Diff	SB	15	16	15	30	76
Gen-tie	Easy	LB	5	6	6	10	27
Gen-tie	Easy	MB	11	9	9	21	50
Gen-tie	Easy	SB	15	15	15	30	75
Season Totals			**150**	**150**	**180**	**330**	**810**

Large bird = (LB); Medium bird = (MB); Small bird = (SB). Low = low coble cover; High = high coble cover; Diff = difficult visibility class; Easy = easy visibility class.

Comentado [A3]: Why 0?

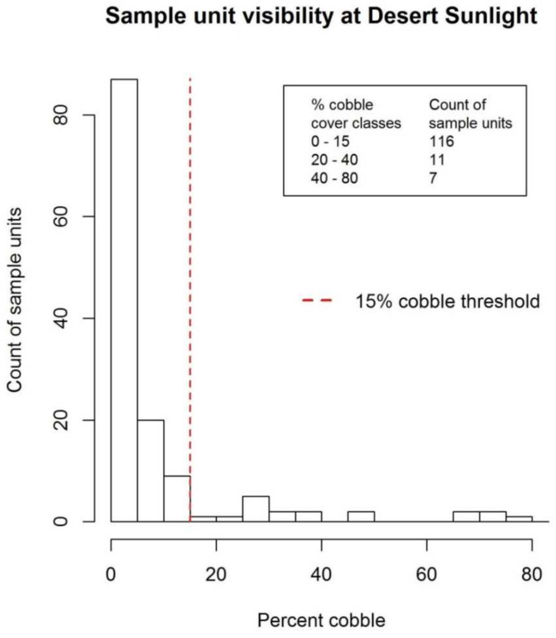

Figure 4. Frequency histogram of sample units (in the arrays only) at Desert Sunlight Solar Farm Project by estimates of cobble cover. Based on this distribution, each sample unit was assigned to one of two classes of cobble cover (<15%; >15%).

2.3.2 Estimating Searcher Efficiency

Searcher efficiency at Desert Sunlight was estimated separately for linear features (the Project fence and the gen-tie line), and the solar arrays, reflecting the different search methods used on arrays and linear features. For linear features, logistic regression models were fit to searcher efficiency data, and AICc was used to compare models. Models including effects of carcass size (three classes), visibility (two classes; gen-tie only), and season were compared to each other and the null (i.e., intercept only) model. Once the most supported model was chosen and appropriate classes identified, searcher efficiency, or the proportion of carcasses detected, *p*, was calculated for each class using the following equation:

$$p = \frac{Number\ of\ Carcasses\ Observed}{Number\ of\ Carcasses\ Available}$$

The data for this analysis included all searcher efficiency trial carcasses from the 2015 – 2016 monitoring year.

For the solar arrays, searcher efficiency was evaluated using a distance sampling approach (Buckland et al. 1993). Distance sampling assumes perfect detection on the transect line (at distance = 0), an assumption that is likely valid in the solar arrays given the relatively flat & vegetation-free nature of the soil surface. A curve is fitted to the observed carcass data that predicts probability of detection as a function of distance from the transect line. The mean value of this function over a specified distance, *w,* is equal to the average searcher efficiency for a transect of width *w*. The mean value of the detection curve is the integral of the detection function calculated between 0-m and the maximum survey distance (*w;* half the width of the solar array row), divided by the maximum survey distance:

$$p = \frac{\int_0^w f(x)dx}{w},$$

where f(x) is the detection function evaluated at distance, *x*.

One departure in the methods used here, relative to the methods presented in Buckland et al. (1993), was that for this study the detection function was estimated using trial carcasses, which meant that there were both presence (detected) and absence (not detected) data available to fit the detection function (Figure 5, 6, and 7). The availability of both presence and absence data means that the detection function can be estimated using only trial carcasses whose distribution is known. Therefore the detection function, the average searcher efficiency among the arrays, and the final fatality estimate within the arrays are all insensitive to the spatial distribution of carcasses within individual arrays, and the overall searcher efficiency estimate is valid even if the distribution of carcasses among the arrays is not uniform.

Distances of trial carcasses (trials both found and missed) from the transect line were used to fit half-normal, exponential, and hazard rate distribution detection functions for searches among the arrays, which are all commonly used functions for distance sampling surveys (Buckland et al. 1993). The fit of detection functions were compared using AICc and each model was fit with covariates season, carcass size, cobble cover class), and without. Model fits that indicated searcher efficiency increasing at greater distances (n = 54 of 312 candidate models) were excluded from consideration. Size classes were evaluated separately: small bird searcher efficiency was best described by a hazard rate detection function and a model that included cobble cover and split seasons into fall and spring/summer/winter (Figure 5). Medium bird searcher efficiency was best described using an exponential detection function and differed between winter and spring/summer/fall (Figure 6). Large bird searcher efficiency was best described using a uniform detection function and differed between spring/fall and summer/winter (Figure 7).

Comentado [A4]: What does this mean?

Because the solar arrays were surveyed by searchers who walked down both sides of the rows of panels, the width of the search transect was specified as half the width of the rows of panels. For larger birds, there is almost certainly a non-zero detection probability beyond this distance but the bias that occurs by ignoring this non-zero detection probability is conservative (i.e., the searcher efficiency is underestimated). Some solar arrays have row widths of 70 m (search transect width of 35 m) and some have row widths of 140 m (search transect width of 70 m). The weighted average searcher efficiency is calculated based on the number of panel rows of each length in the survey sample:

$$p_{weighted\ average} = \frac{n_{70}}{n} \times \frac{\int_0^{35} f(x)dx}{35} + \frac{n_{140}}{n} \times \frac{\int_0^{70} f(x)dx}{70},$$

where n_{70} is the number of 70-m rows in the sample, n_{140} is the number of 140-m rows in the sample, and *n* is the total number of rows in the sample. Searcher efficiency was higher for the arrays with a width of 70 m, and overall searcher efficiency was estimated as a weighted average based on the proportions of 70-m arrays and 140-m arrays in the sample units.

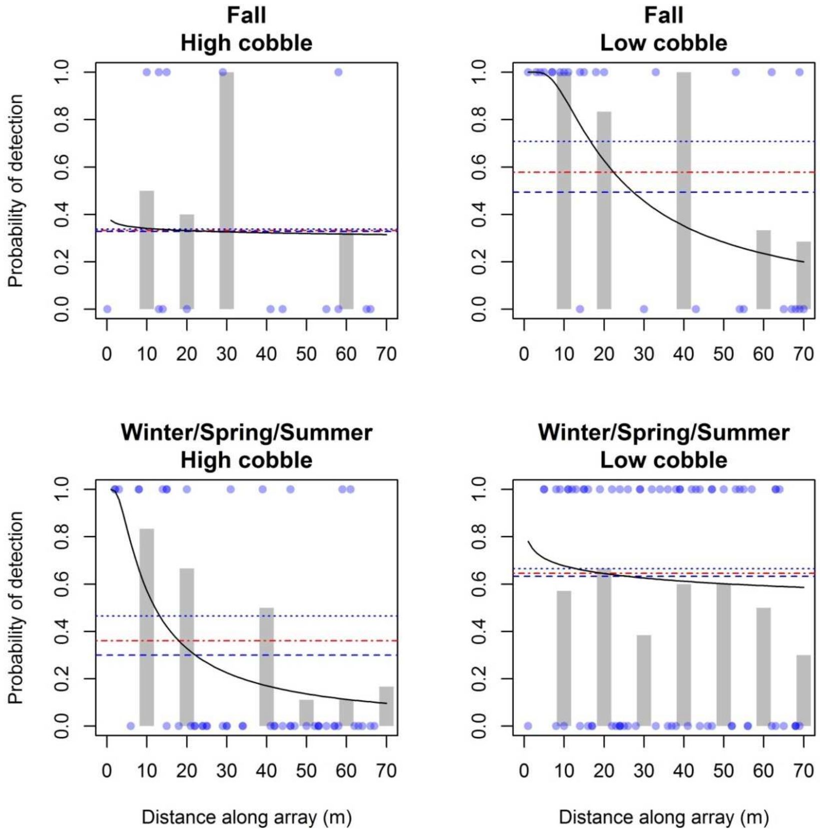

Figure 5. Estimated detection probabilities for small bird carcasses by cobble cover class and season during the 2015 – 2016 monitoring year (March 1, 2015 – February 28, 2016) at the Desert Sunlight Solar Farm Project, Riverside County, California. Distance sampling was used when searching solar arrays only. Average probability of detection over 70-m (arrays relying on a 35-m viewshed) and 140-m (arrays relying on a 70-m viewshed) panel rows in solar arrays are presented.

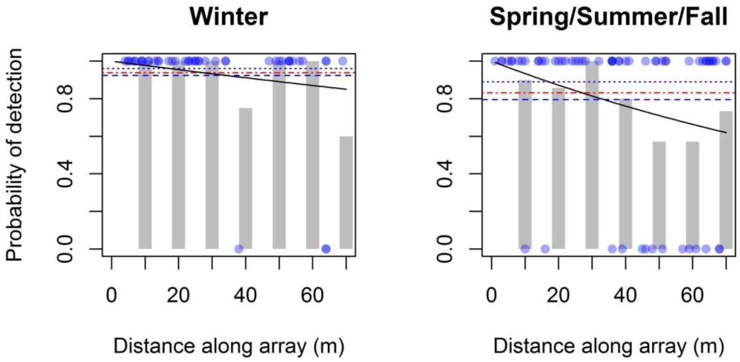

Figure 6. Estimated detection probabilities for medium bird carcasses by season during the 2015 – 2016 monitoring year (March 1, 2015 – February 28, 2016) at the Desert Sunlight Solar Farm Project, Riverside County, California. Distance sampling was used when searching solar arrays only. Average probability of detection over 70-m (arrays relying on a 35-m viewshed) and 140-m (arrays relying on a 70-m viewshed) panel rows in solar arrays are presented.

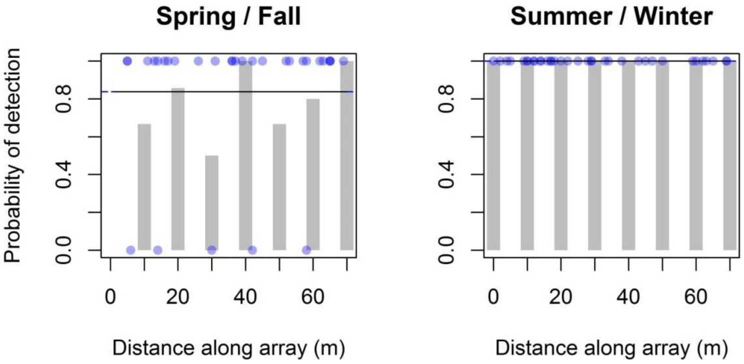

Figure 7. Estimated detection probabilities for large bird carcasses by season during the 2015 – 2016 monitoring year (March 1, 2015 – February 28, 2016) at the Desert Sunlight Solar Farm Project, Riverside County, California. Distance sampling was used when searching solar arrays only. Average probability of detection over 70-m (arrays relying on a 35-m viewshed) and 140-m (arrays relying on a 70-m viewshed) panel rows in solar arrays are presented.

2.4 Fatality Estimator

Fatality rate estimation is a complex task due to several variables inherent to every fatality monitoring study. Carcasses may persist for variable amounts of time due to local scavenger activity or environmental conditions leading to carcass degradation over time. Carcasses and feather spots were also detected with varying levels of success based on carcass characteristics and ground cover (e.g., vegetated areas underneath the gen-tie line versus cleared areas beneath solar panels). For these reasons, it is generally inappropriate to draw conclusions based on the raw number of fatalities alone. The desire to estimate fatalities given these variables has driven the development of several statistical methods for estimating fatalities (e.g., Smallwood 2007, Huso 2010, Korner-Nievergelt 2011). All of these fatality estimation methods share a similar underlying model. Generally, the fatality estimation for a given site may be written as:

$$F=C/rp,$$

where F is the total number of fatalities, C is the number fatalities detected and included in fatality estimation, r is the probability a carcass is un-scavenged and available to be found at the end of the search interval, and p is the probability of detecting a carcass (Huso 2010). Huso (2010) describes the use of a binomial model to estimate the probability of carcass detection in the present study. The binomial carcass detection model was used to calculate fatalities at Project linear features (fence, overhead lines) and the weighted average probability of detection based on distance sampling (described above) was used to estimate probability of detection within the solar arrays.

All fatality estimates were calculated using the Huso estimator (modified to accommodate the distance-sampling based estimate of searcher efficiency in the solar arrays), as well as 90% confidence using bootstrapping (Manly 1997). Bootstrapping is a computer simulation technique that is useful for calculating point estimates, variances, and confidence intervals for complicated test statistics. A total of 1,000 bootstrap replicates was used for each variable including of searcher efficiency (p), probability of a carcass persisting to the next search ($\hat{r}$), adjusted search interval and observed fatalities. From these bootstrap samples, the probability of available and detected was calculated and applied to the bootstrapped observed fatalities. The lower 5th and upper 95th percentiles of the 1,000 bootstrap estimates provide estimates of the lower limit and upper limit of an approximate 90% confidence interval on all estimates.

2.5 Incidental Reporting

Some detections were outside standardized search areas, or were within search areas but not observed during standardized searches. Such detections were found by either WEST avian biologists or operations personnel and were considered “incidental” detections. When found by operations personnel, these detections were reported to WEST avian biologists for documentation. Data on incidental detections are reported here, as well as in the Desert Sunlight SPUT Avian Injury and Mortality Report Forms, March 2015 - February 2016. All detections made in search areas during the reporting period were included in fatality estimates, regardless of whether they were detected incidentally or during searches.

3 MONITORING RESULTS

3.1 Summary of Avian Detections

Figures 6 – 9 show the location of detections found during the monitoring year. Detailed areas of carcass locations along the gen-tie line are provided in Appendix A. During the 2015 – 2016 monitoring year, a total of 149 avian detections (including all stranded and injured birds and incidental detections) of 19 guilds and including 53 identified species were recorded (Table 4; Figure 8, 9, 10, and 11). The most numerous detection of an identified species was of American coot (*Fulica americana*) with 12 detections, followed by mourning dove (*Zenaida macroura*; n = 6). The highest detection in the solar arrays were American coot (n = 9), followed by western grebe (*Aechmophorus occidentalis*; n = 5) with no other species with more than four detections. The only species observed along the fence were American coot (n = 1), common raven (*Corvus corax*; n = 1), common loon (*Gavia immer*; n = 1), white-winged dove (*Zenaida asiatica*; n = 1), and mallard (*Anas platyrhynchos*; n = 1). Eurasian collared-dove (*Streptopelia decaocto*; n = 4) and orange-crowned warbler (*Oreothlypis celata*; n = 3) were the species with the most detections along the gen-tie/road. No bats were detected during the 2015 – 2016 monitoring year. For fresh carcasses, body weights and weather conditions the preceding nights are described in Appendix B.

The majority of detections (n = 98, or 65.8% of total detections) occurred at the solar arrays (Tables 4, 5, and 6). Forty-one detections (27.5%) occurred along the gen-tie line, seven along the fence and three at buildings. There do not appear to be major concentration areas of detections within the solar arrays (Figures 6, 7). One hundred thirteen detections (75.8%) were made during standardized carcass searches and 36 (24.2%) were documented as incidentals.

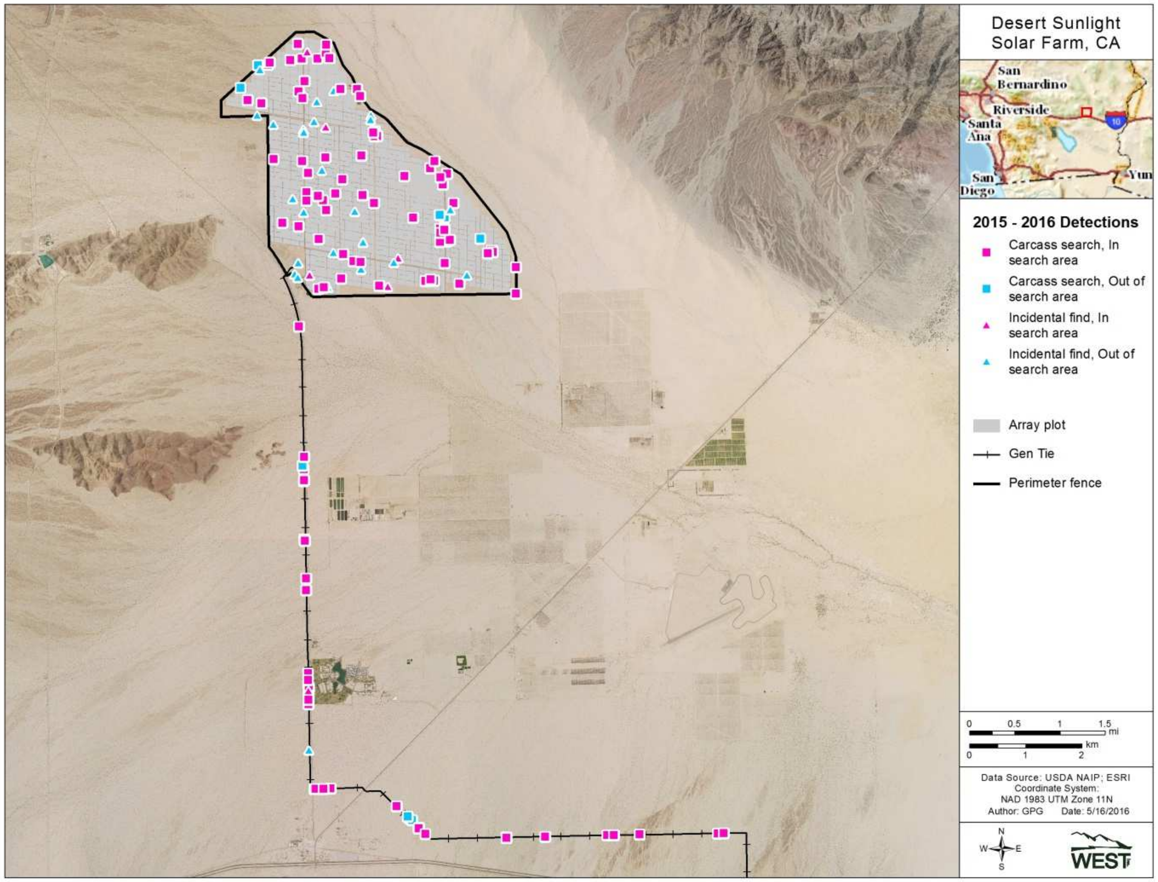

Figure 8. Areas of standardized searches and detections (those made during searches and those made incidental to operations and maintenance) at the solar field, visitor center, overhead lines within the fence, and the gen-tie line at Desert Sunlight Solar Farm Project during the 2015 – 2016 monitoring year (March 1, 2015 – February 28, 2016).

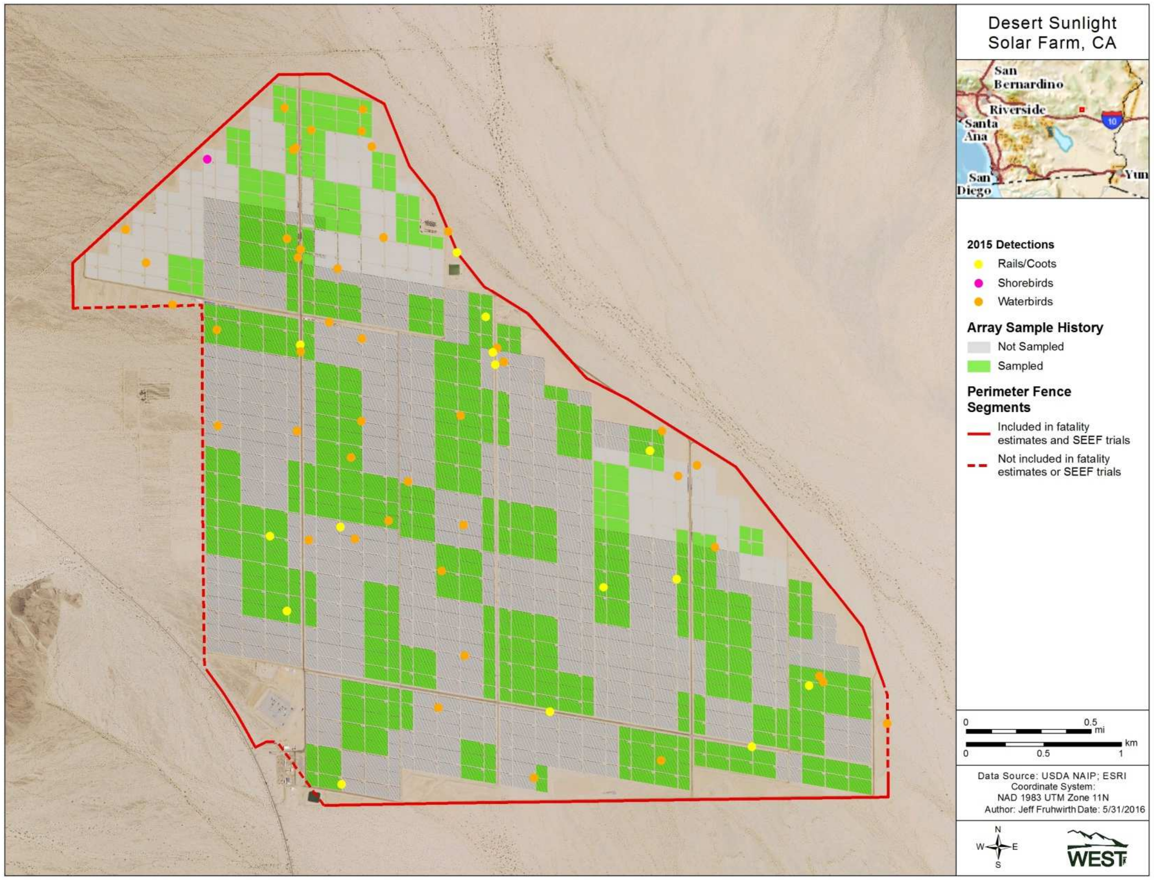

Figure 9. Location of water-associated bird carcass detections throughout the solar field, visitor center, and overhead lines within the fence at Desert Sunlight Solar Farm Project during the 2015 – 2016 monitoring year (March 1, 2015 – February 28, 2016).

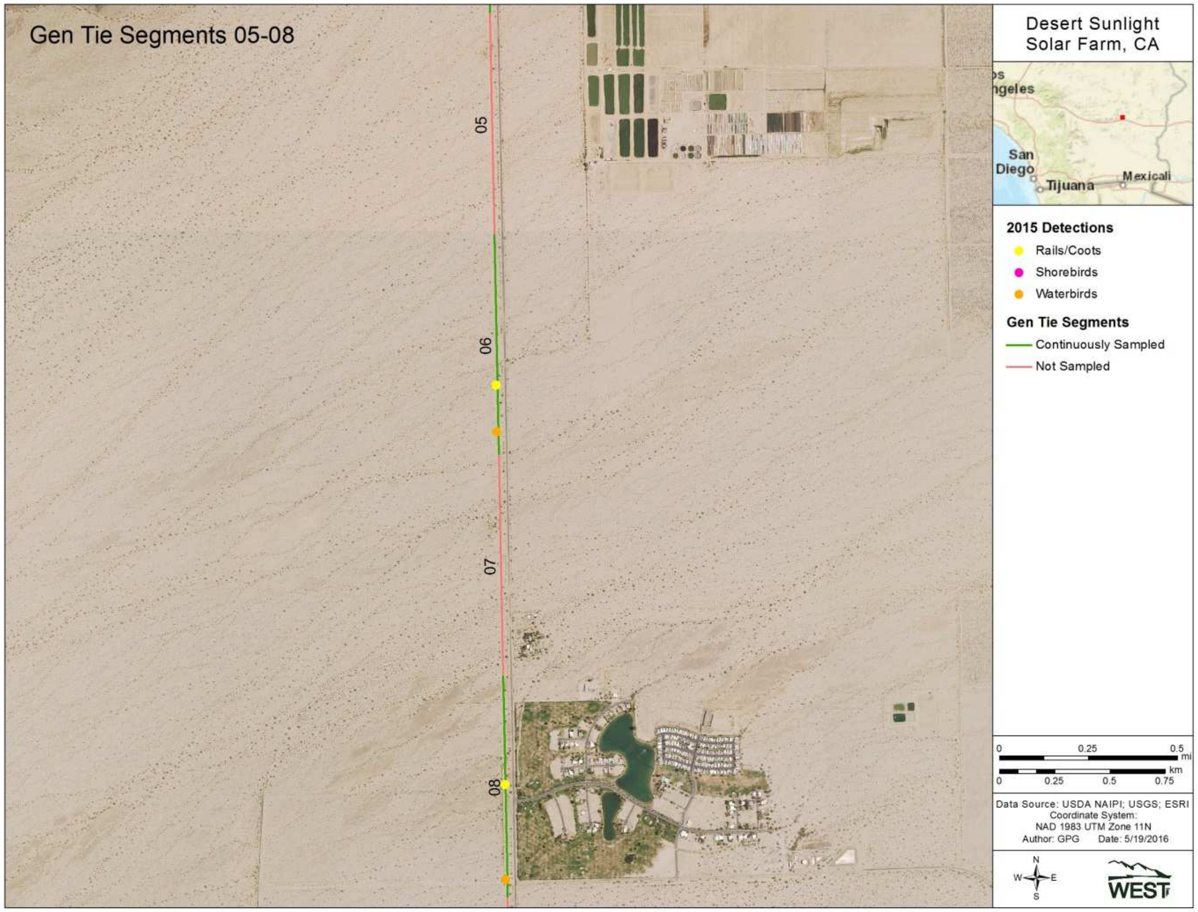

Figure 10. Location of water-associated bird carcass detections along the generation tie line at Desert Sunlight Solar Farm Project during the 2015 – 2016 monitoring year (March 1, 2015 – February 28, 2016).

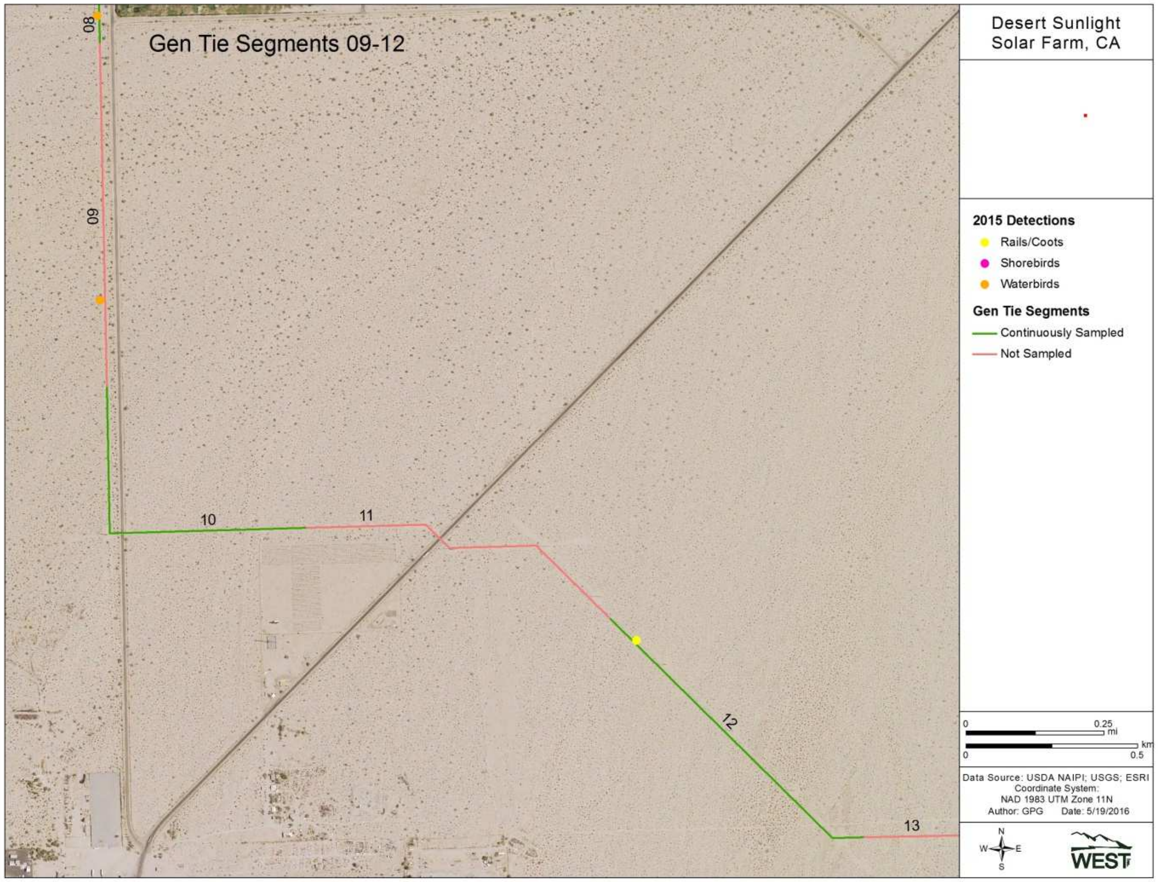

Figure 11. Location of water-associated bird carcass detections along the generation tie line at Desert Sunlight Solar Farm Project during the 2015 – 2016 monitoring year (March 1, 2015 – February 28, 2016).

Table 4. Number of individual bird detections, by species, found during scheduled searches and incidentally during the 2015 – 2016 monitoring year (March 1, 2015 – February 28, 2016) at the Desert Sunlight Solar Farm Project, Riverside County, California.

Common Name	Scientific Name	Migration Behavior*	Guild	Solar Array	Fence	Gen-tie Line	Visitor Center	Total
			Water-associated birds

[1] Ring-necked pheasants are used for bias trials and the two detections were likely from trial carcasses; however, ring-necked pheasants have been reported in Riverside County, CA south of the Project area near the Salton Sea (eBird 2015). Thus, we cannot be certain that these detections were exclusively from trial carcasses.

[2] See literature cited for migration behavior references; information for most species was taken from the respective species accounts found in The Birds of North America website (BNA 2016); where information on migration behavior was lacking in BNA accounts, Newton (2008) or Murray (2004) were used.

3.2 Suspected Cause of Avian Mortality

Most carcasses observed do not show clear signs of cause of death (Table 5 and 6). Evidence of collision as cause of death could include broken neck or beak, or bird imprint in the dust on a solar panel, but only a few carcass incidents had such evidence. There were 149 birds detected during the 2015 – 2016 monitoring year. Most of the detections were assigned an unknown cause of death; however 19.5% were suspected to be due to collision (with gen-tie, fence and solar arrays), 5.4% stranded, and 1.3% were due to predation (Table 5). There were 66 water-associated birds detected during the 2015 – 2016 monitoring year. Most were assigned unknown cause of death; however 10.6% were stranded, and 9.1% were likely collision-caused (Table 6).

Table 5. Total bird detections (including incidentals) by Project component and suspected cause of death during the 2015 – 2016 monitoring year (March 1, 2015 – February 28, 2016) at the Desert Sunlight Solar Farm Project, Riverside County, California.

	Suspected Cause of Death*				
Project Component	**Collision**	**Predation**	**Stranded**	**Unknown**	**Percent of Total Avian Fatalities**
Fence	1	0	0	6	4.7
Building	0	0	0	3	2.0

Solar arrays	13	0	8	77	65.8
Percent of Total	**19.5**	**1.3**	**5.4**	**73.8**	**100.0**

* Suspected cause of death was assigned based on evidence available on the detection, evidence available on Project infrastructure, and proximity of detection to Project infrastructure. Detections that had evidence of scavenging and lacked evidence on Project infrastructure were assigned as "unknown" because it cannot be determined whether the event was caused by predation or interaction with Project infrastructure. Detections that were intact (i.e., no evidence of scavenging) and located in close proximity to Project infrastructure (e.g., found directly beneath overhead lines) had a suspected cause of death attributed to the respective Project component. However, there is substantial uncertainty associated with cause of death assignments because no events were directly observed.

Table 6. Total waterbird detections (including incidentals) by Project component and suspected cause of death during the 2015 – 2016 monitoring year (March 1, 2015 – February 28, 2016) at the Desert Sunlight Solar Farm Project, Riverside County, California.

* Suspected cause of death was assigned based on evidence available on the detection, evidence available on Project infrastructure, and proximity of detection to Project infrastructure. Detections that had evidence of scavenging and lacked evidence on Project infrastructure were assigned as “unknown” because it cannot be determined whether the event was caused by predation or interaction with Project infrastructure. Detections that were intact (i.e., no evidence of scavenging) and located in close proximity to Project infrastructure (e.g., found directly beneath overhead lines) had a suspected cause of death attributed to the respective Project component. However, there is substantial uncertainty associated with cause of death assignments because no events were directly observed.

3.3 Temporal Patterns of Avian Detections

Both spring and fall migration seasons were seven-day searches, while summer and winter had a 21-day average search interval, so interpretations of temporal patterns should keep those differences in mind. The number of detections recorded per day represents those discovered during standardized carcass searches as well as those discovered incidentally. For each day in which there were six or more detections made, an Avian Injury & Mortality Report form (in accordance with Special Utilities Permit Condition H.1(c)) was submitted within 24 hours to the USFWS, BLM, and CDFW. The 2015 – 2016 monitoring year was characterized by a peak in avian detections during the fall season. The number of avian detections recorded daily during the 2015 – 2016 monitoring year ranged from zero to six (Figure 12). On September 22, 2015, six detections were reported. During all other survey days, five or fewer birds were detected.

The highest peaks in avian detections at the arrays and along the gen-tie occurred during the fall season, while there was no apparent pattern observed along the fence or at buildings as only a few were detected at these locations (Figure 13). The greatest number of avian detections occurred during the month of October (Figure 13; n = 44) followed by September (n = 38), with waterbird and waterfowl detections greatest during the same two months (Figure 13).

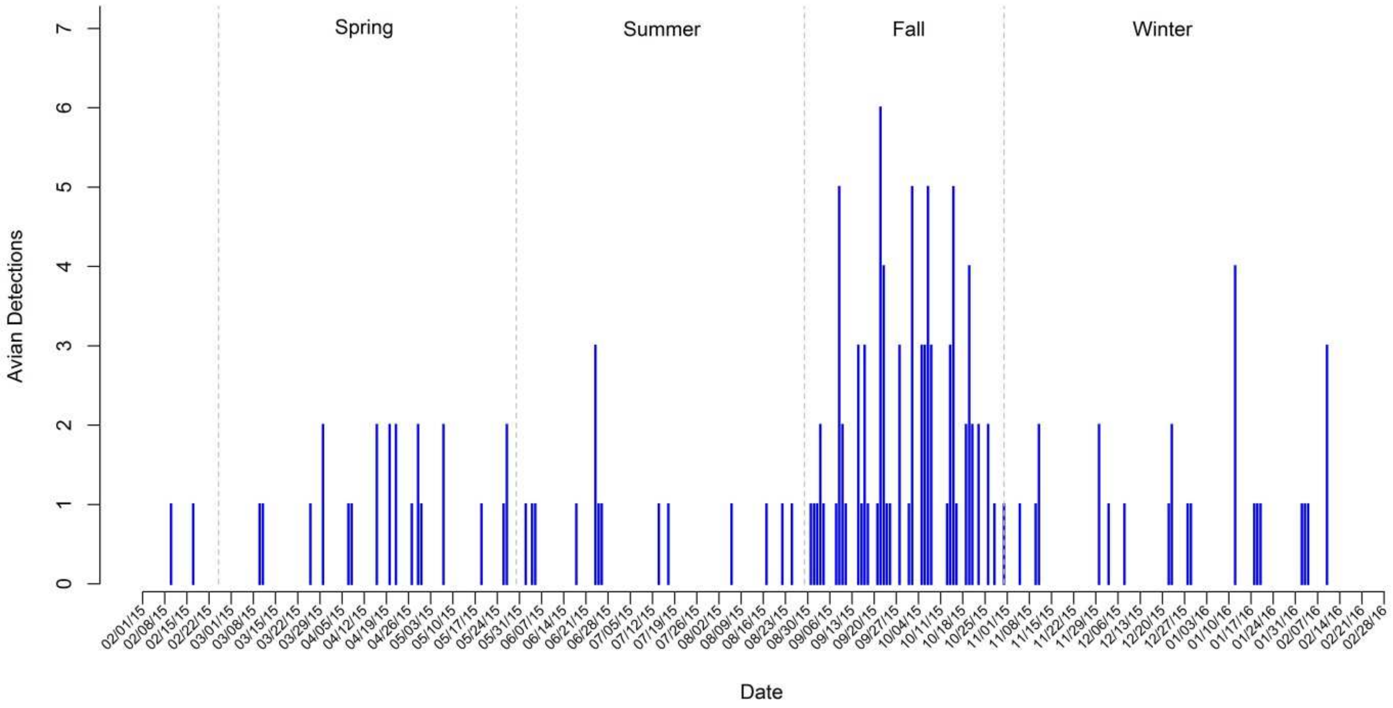

Figure 12. Total count of detections (including incidentals) by date during the 2015 – 2016 monitoring year (March 1, 2015 – February 28, 2016) at the Desert Sunlight Solar Farm Project, Riverside County, California.

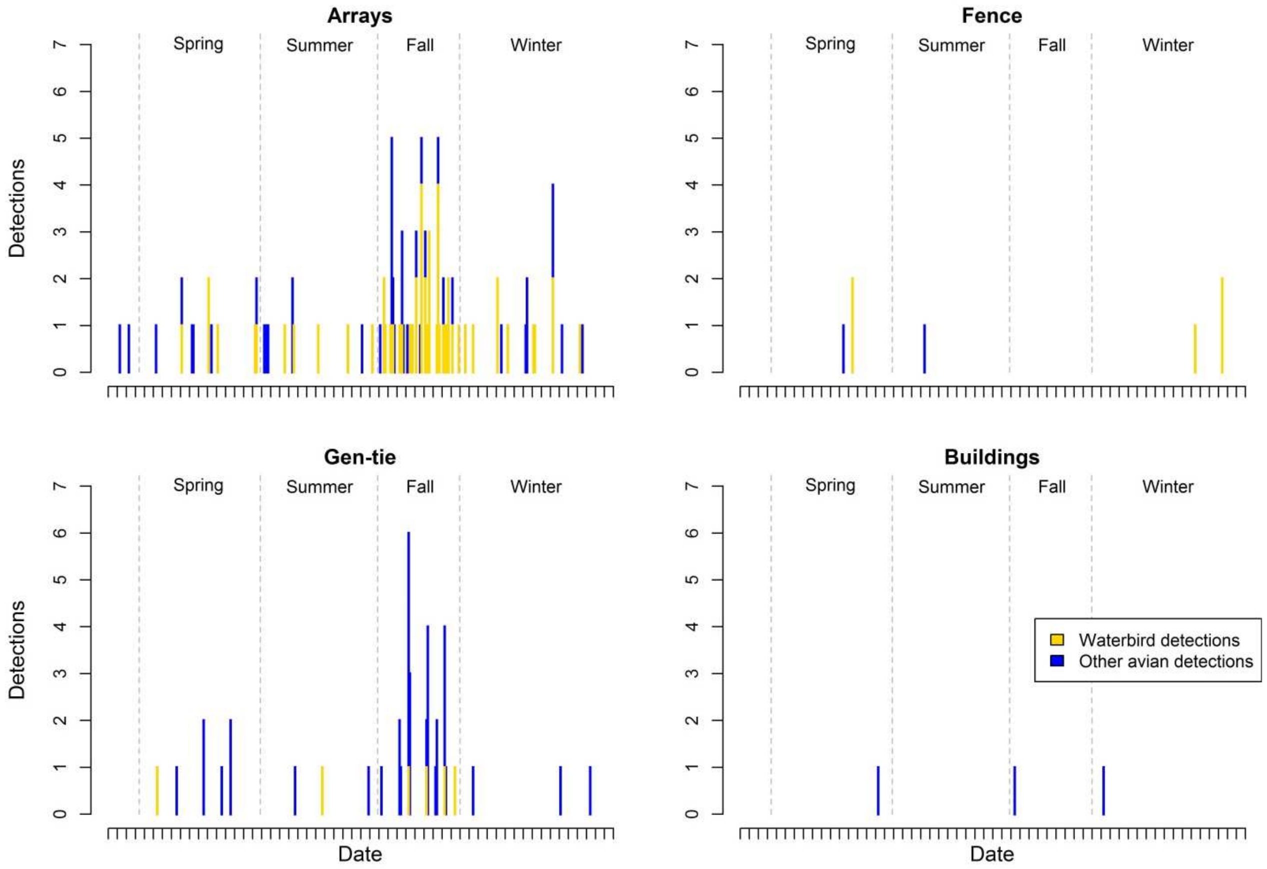

Figure 13. Total count of detections (including incidentals) by date for both waterbirds/waterfowl detections and all avian detections during the 2015 – 2016 monitoring year (March 1, 2015 – February 28, 2016) at the Desert Sunlight Solar Farm Project, Riverside County, California.

3.4 Spatial Distribution of Avian Detections

3.4.1 Detections by Project Component

During the 2015 – 2016 monitoring year, detections were documented from the solar arrays, the Visitor Center, the fence, and the gen-tie line (Tables 4 and 5). There were 98 detections (65.8% of all detections) at the solar arrays. Forty-one detections (27.5% of annual total) were along the gen-tie line, seven were along the fence (4.7% of annual total) and three detections (2.0% of annual total) were at the Visitor Center. The majority of non-water-associated birds (n = 43; Table 7) and water associated birds (n = 55; Table 8) were detected at the solar arrays, and is not unexpected given the large spatial extent of the arrays (over 4000 acres).

Table 7. Total non-waterbird detections by Project component and detection category during the 2015 – 2016 monitoring year (March 1, 2015 – February 28, 2016) at the Desert Sunlight Solar Farm Project, Riverside County, California. Only carcasses found within search areas were included in fatality estimates.

Project Component	Inside carcass search area		Outside carcass search area

Only carcasses found within search areas were included in fatality estimates.

Project Component	Inside carcass search area		Outside carcass search area	
	Carcass search	Incidental	Carcass search	Incidental
Fence	3	0	1	1
Buildings	0	0	0	0
Gen-tie line	5	0	0	1
Solar arrays	34	6	2	13
Total	**42**	**6**	**3**	**15**

3.4.2 Detections at solar collector assemblies

Upon ocular examination, fatalities among the solar arrays appear evenly dispersed throughout the Project site (Figure 14). The distance between the average location of the search areas and the average location of fatalities found inside search areas is 73 meters suggesting no obvious concentration of fatalities in a particular direction (e.g. more fatalities towards the west or towards the south side of the facility).

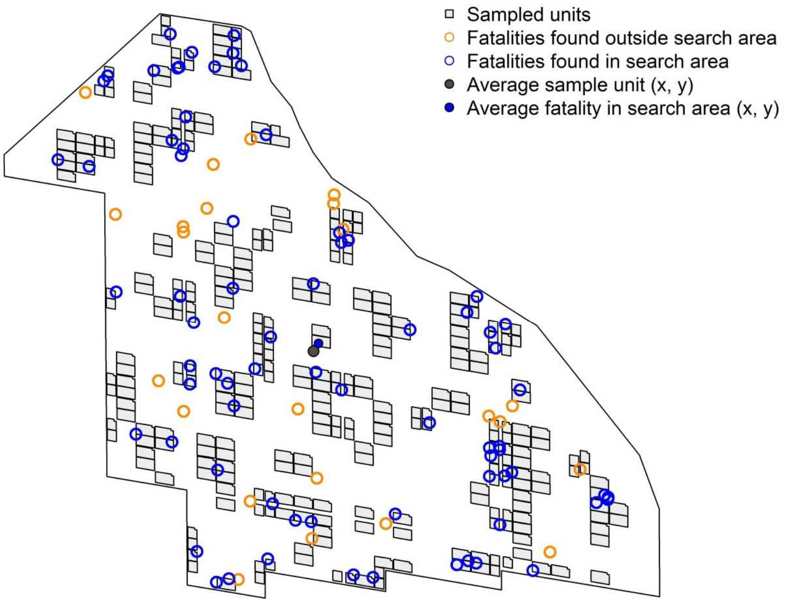

Figure 14. Spatial distribution of carcass search and incidental detections from SCAs during the 2015 – 2016 monitoring year (March 1, 2015 – February 28, 2016) at the Desert Sunlight Solar Farm Project, Riverside County, California.

3.4.3 Feather Spot Detections

Thirty-eight (25.5%) of the 149 detections made during the 2015 – 2016 monitoring year consisted only of feather spots. Along the gen-tie, 14 of 41 detections (34.1%) were feather spots. Twenty-two of 98 detections (22.5%) in the solar arrays were feather spots. Along the fence, two of seven total detections (28.6%) were feather spots.

3.5 Detections of Injured or Stranded Birds

There were six detections of stranded or injured birds during the 2015 – 2016 monitoring year, each of which occurred during the fall monitoring period. Three injured birds were detected within the solar arrays (ruddy duck [*Oxyura jamaicensis*], western grebe [*Aechmophorus occidentalis*], and mourning dove [*Zenaida macroura*]). Three stranded but uninjured birds were detected in the arrays (common loon [*Gavia immer*]) and ruddy duck and eared grebe [*Podiceps nigricollis*]). The injured mourning dove and ruddy duck were transported to wildlife rehabilitation facilities; the ruddy duck was released by the rehabilitator on the same day. The injured western grebe died before it got to a rehabilitation facility. The stranded ruddy duck, eared grebe, and common loon were evaluated for a short period for injuries and general stress and when none were observed, released at Lake Tamarisk.

3.6 Summary of Bat Detections

No bats were detected during the 2015 – 2016 monitoring year.

3.7 Carcass Persistence Trials

Data from carcass persistence trials were available from all four seasonal monitoring periods within the solar arrays and along the gen-tie line. A total of 275 carcasses were available for fitting the model.

Using carcass persistence data from the 2015 – 2016 monitoring year, survival models were fitted separately for each size class for relative quality using the corrected AICc score, as suggested in Huso (2010). The model with the lowest AICc is typically chosen as the “best” model relative to other models tested; however, any model within two AICc points of the best model is considered competitive with the best model (Burnham and Anderson 2004).

Models were fit to each size class separately to allow for the selection of different model distributions and covariate combinations to achieve the best fit for each size class. Model comparisons using AICc suggested that season and Project component location (whether at the solar field or at the overhead lines) are important predictors of carcass persistence for small, medium and large birds.

Both Project component location and season were important in the large bird persistence model. For large birds, the AICc suggested that a seasonal covariate with two categories, spring and fall data pooled and winter and summer data pooled together was not the top rated model, but within two AICc points from the top model. This model was chosen because it has similar predictive ability as the top model but also has fewer parameters to estimate. For medium birds, the best predictive model included the main effects of Project component location and season. The AICc suggested that a seasonal covariate with two categories, spring and summer data pooled and fall and winter data pooled together was the best predictive model for medium birds. The best model for small birds included the main effects of Project component location, season (with no pooling), and an interaction between Project component location and season. The best models for small, medium, and large birds followed a lognormal, Weibull, and loglogistic distribution respectively (Table 9).

Table 9. Top five carcass persistence models for each size class from the AICc model selection process. (bold) indicates chosen model. Sp = spring, Su = summer, Fa = fall, Wi = winter, and Δ = change. The covariate 'season' has no seasonal grouping.

Size	Model Predictors	Distribution	AICc	ΔAICc
Small Birds	**Project (Proj.) Location + season + Proj. Location * season**	**Lognormal**	**596.66**	**0**
	Proj. Location + season + Proj. Location * season	Exponential	597.04	0.38
	Proj. Location + season + Proj. Location * season	Loglogistic	597.07	0.41
	Proj. Location + season + Proj. Location * season	Weibull	598.76	2.10
	Proj. Location + season	Lognormal	600.00	3.34
Medium Birds	**Proj. Location + Sp/Su & Fa/Wi**	**Weibull**	**466.35**	**0**
	Proj. Location + Sp/Su & Fa/Wi	Loglogistic	467.59	1.24
	Proj. Location + Sp/Su & Fa/Wi	Lognormal	467.74	1.39
	Proj. Location + Sp/Su & Fa/Wi + Proj. Location * Sp/Su & Fa/Wi	Weibull	468.54	2.19
	Proj. Location season + Proj. Location * season	Weibull	469.65	3.30
Large Birds	**Proj. Location + season + Proj. Location * season**	**Loglogistic**	**258.71**	**0**
	Proj. Location + season + Proj. Location * season	Lognormal	259.29	0.58
	Proj. Location + Sp/Fa & Su/Wi	Loglogistic	259.34	0.63
	Proj. Location + Sp/Fa & Su/Wi	Lognormal	260.40	1.69
	Proj. Location + Sp & Su/Fa/Wi	Loglogistic	260.91	2.20

The sample size for the intercept of each of the three models was 135, 90 and 50 for small, medium, and large trial carcasses respectively.

The average probability that a carcass at the solar field or a carcass along the gen-tie persists for an average search interval (approximately 7 days for spring and fall; 21 days for summer and winter), is provided for each season and size class in Table 10. Mean (median) removal time within the solar field was 4.9 (6.0) days during spring, 12.7 (12.6) during summer, 2.5 (1.5) during fall, and 6.5 (6.0) during winter for small carcasses; 36.0 (27.8) days during spring, 36.0 (24.3) during summer, 12.2 (18.0) during fall, and 12.2 (6.8) during winter for medium carcasses; and 58.3 (31.0) days during spring, 13.7 (30.0) during summer, 58.3 (30.0) during fall, and 13.7 (5.1) during winter (Table 11). At the overhead lines, removal time was 0.8 (0.5), 0.8 (0.5), 0.4 (0.5), and 2.3 (2.5) for small birds during spring, summer, fall, and winter respectively. For medium birds, mean (median) removal time at the overhead lines was 14.4 (2.0), 14.4 (15.8), 4.9 (1.5), and 4.9 (2.5) days during spring, summer, fall, and winter respectively. Mean (median) removal time for large birds was 5.8 (19.0), 1.4 (0.5), 5.8 (3.5), and 1.4 (3.5) days during spring, summer, fall, and winter respectively (Table 11). Figure 15 shows the proportion of trial carcasses remaining as a function of days since placement and carcass model covariate (component location and/or season).

Comentado [A5]: Less than the 7 day and significantly less than 21 day search interval.

Table 10. Average probability of carcass persistence to the next search (search interval approximately 7 days during spring and fall migration periods, and 21 days during summer and winter non-migration periods)

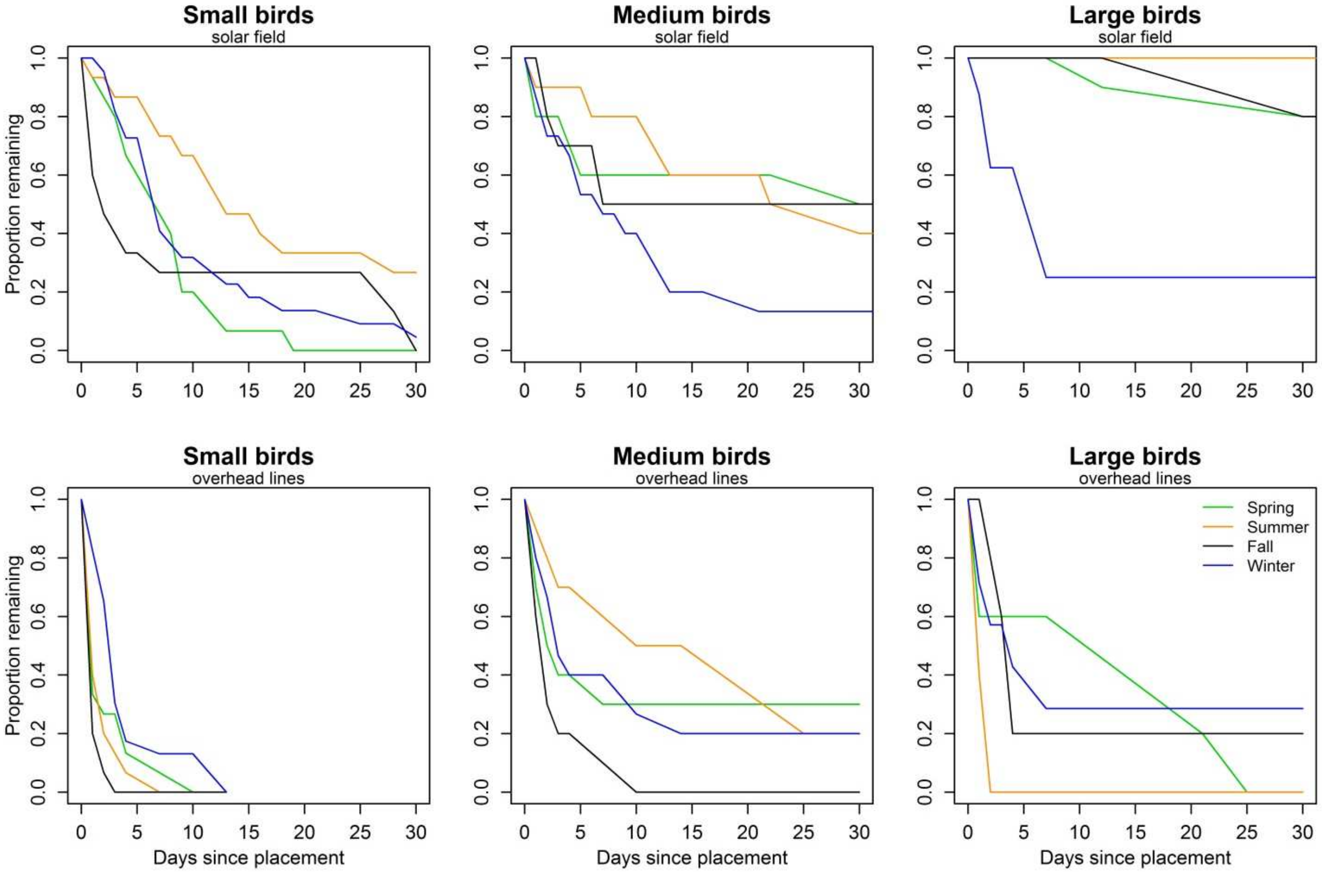

Figure 15. Proportion of trial carcasses remaining as a function of days since placement and carcass size class during the 2015 – 2016 monitoring year (March 1, 2015 – February 28, 2016) at the Desert Sunlight Solar Farm Project, Riverside County, California. Sample size used to produce each panel of the above figure was n = 67, 45, and 28 for small, medium, and large birds at the solar field and 68, 45, and 22 small, medium, and large birds at the overhead lines.

3.8 Searcher Efficiency Trials

During the reporting period, a total of 810 searcher efficiency trials were placed at the Project. Most trials were available to be found, but some disappeared before or during the trial. Overall, 360 trials were placed in the solar arrays and 336 were available to be found; 150 trials were placed along the perimeter fence (inner perimeter only) and 148 were available to be found; and 300 trials were placed along the gen-tie line and 270 were available to be found. Three observers conducted searches at the Project during fall. Searcher efficiency trials were conducted on each observer in approximate proportion to the number of searches they conducted at the Project, as follows: Sarah N. (number of trials available to be found: 281), Jennifer J. (223), Wanda B. (77), Darin B. (71), David G. (58), Pamela B. (27), Anika M. (nine), and Frank M. (eight). All trials were included in estimation of searcher efficiency. These numbers were generally in proportion to the amount of searching conducted by these biologists.

For the solar arrays, searcher efficiency was modeled separately for small, medium, and large birds. The best model for each carcass size is presented in Table 12 below. Within the solar arrays, searcher efficiency for small birds was influenced by cobble cover and season: small birds in high cobble cover in the fall had a searcher efficiency of 33.2% (CI: 13.3 – 63.9%; n = 15) and small birds in low cobble cover in the fall had a searcher efficiency of 57.8% (CI: 39.0 – 77.7%; n = 27; Table 13). Searcher efficiency for small birds in high cobble cover during winter, spring and summer was 36.0% (CI: 21.1 – 45.4%; n = 50), and small birds in low cobble cover during winter, spring and summer had a searcher efficiency of 64.5% (CI: 44.5 – 63.4%; n = 70). For medium birds, searcher efficiency within the solar arrays was similar across cobble cover classes but differed by season: in winter, medium bird searcher efficiency was 94.0% (CI 87.5 – 98.5%; n = 45), and in spring, summer and fall, medium bird searcher efficiency was 83.2% (CI: 76.5 – 89.8%; n = 63). For large birds, searcher efficiency among the solar arrays differed between migration seasons (spring and fall) and non -migration seasons (summer and winter). Searcher efficiency during spring and fall for large birds was 83.9% (CI: 72.0 – 94.3%; n = 31). Searcher efficiency for large birds during summer and winter was 100% with no variance (n = 35). Sample sizes refer to numbers of trial carcasses that were available to be found, not numbers of trial carcasses that were placed (Figure 5 - 7).

For the fence, the model that included an effect of carcass size, and season (with data from spring and winter pooled and summer and fall pooled) was chosen as the most supported model to estimate searcher efficiency (Table 14). Along the fence, searcher efficiency was 65% (CI: 52 – 77%), 94% (CI: 88 - 100%), and 100%, for small, medium, and large carcasses, respectively during spring and winter and 87% (CI: 77 – 97%), 98% (CI: 96 – 100%), and 100% for small, medium, and large carcasses respectively during summer and fall (Table 13).

For the gen-tie line, the chosen model included main effects of size, season (with data from spring and summer data pooled and fall and winter pooled), and visibility class, with an interaction between visibility class and season (Table 14). It ranked second by AICc but was only 0.59 AICc points from the top model. It was chosen because it has similar predictive performance as the top model, but with fewer parameters to estimate. For the easy visibility class, searcher efficiency was 67% (CI: 53 – 81%), 89% (CI: 80 – 95%), and 89% (CI: 80 – 96%) for small, medium, and large carcasses, respectively during spring and summer and 57% (CI:46 – 68%), 84% (CI: 75 – 91%), and 85% (CI: 73 – 93%) for small, medium, and large birds respectively during fall and winter (Table 13). For the difficult visibility class, searcher efficiency was 75% (CI: 62 – 86%), 92% (CI: 86 – 97%), and 92% (CI: 84 – 97%) for small, medium, and large birds respectively during spring and summer and 33% (CI: 22 – 44%), 65% (CI: 53 – 77%), and 67% (CI: 51 – 82 %) for small, medium, and large birds respectively during fall and winter (Table 13). A summary of searcher efficiency estimates are reported in Appendix C.

3.9 Fatality Estimates

Fatality estimates were calculated separately for each component (solar arrays, fence, and overhead lines). There were 149 detections during the 2015 – 2016 monitoring year. Fatalities found in the sample standardized search areas that were estimated not less than twice the length of the search interval were included. This conservative definition was used due to uncertainty in aging carcasses and should result in a positive (overestimate) bias. Detections used in the analysis, bias corrections, fatality estimates, and 90% confidence intervals are detailed in Appendix C.

Using the Huso (2010) fatality estimator, during the 2015 – 2016 monitoring year, there were an estimated total of 1,328 bird carcasses (CI: 1,007 – 2,303) at the Project (all components combined). There were an estimated 53 (CI: 28 – 85) large birds, 336 (CI: 246 – 449) medium birds, 881 (CI: 566 – 1,843) small birds, and 58 (CI: 22 – 143) birds of unknown size at the Project (all components combined; Table 15).

The model estimates 628 (CI: 496 – 951) bird carcasses (152/1000 acres, 1.16/nameplateMW) at the solar arrays, 688 (CI: 364 – 1,567) along the gen-tie line and 11 (CI: 2 – 26) at the fence. Estimates of fatalities along the gen-tie are heavily influenced by the high rates of scavenging observed during the limited trials at the gen-tie (i.e., large correction factors) and are likely very unreliable. Adjusted fatality estimates for each Project component are provided by guild in Table 16. A complete list of estimates by Project component and carcass size class with confidence intervals is presented in Appendix C.

Table 15. Adjusted fatality estimates by size and guild during the 2015 – 2016 monitoring year (March 1, 2015 – February 28, 2016) at the Desert Sunlight Solar Farm Project, Riverside County, California

4 DISCUSSION

The 2015 – 2016 monitoring year represented the first full year of standardized monitoring at Desert Sunlight. Searcher efficiency and carcass persistence trials were conducted concurrently at the solar arrays, fence lines, and along the gen-tie line. Data from these trials were used to produce fatality estimates adjusted for searcher efficiency and carcass persistence bias. The results provided in each seasonal report were considered preliminary because estimating carcass persistence, searcher efficiency, and adjusted numbers of fatalities within each season represents information based on a limited sample size. For this annual report, the analysis is comprehensive, with data from all four seasons included in the analysis.

4.1 Carcass Persistence and Searcher Efficiency Trials

The degree to which carcasses persist on the landscape depends on a variety of factors reflecting seasonal and inter-annual variation in habitat, climate, and the scavenger community. The composition and activity patterns of the scavenger community often vary seasonally as birds migrate, new juvenile birds and mammals join the local population, and mammalian scavengers variably hibernate or estivate. The scavenger community may also vary substantially from year to year because of variation in annual reproduction and survival related to changes in landscape condition. Climatic conditions that vary seasonally and annually also may contribute to variation in carcass decay and removal rates due to variation in temperatures, solar insolation, wind patterns, the frequency of flooding events, and other factors. Carcass persistence was low along the gen-tie line, while persistence rates were longer within the Project fence. Overall, carcass persistence rates were longer for medium and large birds compared to smaller birds but there was variation by season and Project component. The longer persistence rates for larger sized birds is a consistent result seen in many other studies (Smallwood et al. 2010, and Morrison 2002).

The experimental bias trials themselves may influence scavenging on site. The large number of carcasses used in trials may be attracting scavengers to the Project site and negatively influencing the bias adjustments for the fatality estimates. Scavengers may learn from visual and olfactory cues that carcasses are being placed for trials. Placing carcasses in the early morning, placing fake cameras at locations without carcasses, and varying the clothes of the biologists placing the carcasses are all methods that were used to try to reduce this bias.

Searcher efficiency was influenced by carcass size, season, and cobble cover within the solar arrays. Some of the relationships that were apparent were not always explainable and expected from a biological perspective (e.g. some of the seasonal effects), but were still included in the final models. Consideration for simplifying the models will be given for the 2nd year monitoring data analysis and reporting.

4.2 Fatalities Timing and Guild/Species Composition, and Other Fatality Characteristics

There were no large mortality events (e.g., >30 birds found on a day) during this 2015 – 2016 monitoring period. More detections occurred during the fall season, beginning in early September and continuing through late October. This peak in detections coincides with the fall bird migration period as well as the time when population sizes are typically highest during fledging in the summer. The increased detections in the fall were primarily due to detections of water-associated birds, especially during the month of October. The peak observed during the fall was apparent within both the solar arrays and along the gen-tie. At the solar arrays, the increase in the fall was mostly waterbird species, whereas the fall increase observed along the gen-tie was primarily non-water associated species.

During the 2015 – 2016 monitoring year, the 149 avian detections (including all stranded and injured birds and incidental detections) consisted of 19 guilds and included 53 identified species. The most numerous detection of an identified species was American coot with 12 detections, most of which were at the solar arrays. Mourning dove (n = 6) was the next most commonly detected species. The most numerous detection in the solar arrays was American coot (n = 9), followed by western grebe, with no other species with more than four detections. The only species observed along the fence were American coot (n = 1), common raven (n = 1), common loon (n = 1), white-winged dove (n = 1), and mallard (n = 1). Eurasian collared-dove (n = 4) and orange-crowned warbler (n = 3) were the species with the most detections along the gen-tie/road.

There were no strong spatial patterns observed within the solar arrays or along the fenceline. Along the gen-tie line, there were a few clusters of detections, the majority of which were small bird species.

4.3 Causation

Detections attributed to an unknown cause accounted for approximately 74% of all detections during the 2015 – 2016 monitoring year. Determining a cause of mortality from a feather spot or scavenged bird is challenging because there is rarely visible evidence available on which to determine a cause of death. Especially for passerine species found on the Project, an unknown but potentially measurable number of the carcasses might have been caused by factors other than collision with the Project facilities. Due to this uncertainty of causation, some studies have estimated background fatality estimates at reference or control areas. There have been two studies of background mortality at solar facilities: CVSR and Topaz had conducted background avian fatality monitoring in an effort to assess causation (H.T Harvey and Associates 2014; Althouse and Mead Inc. 2014). These studies were designed to try and quantify the potential degree to which fatalities were likely the result of interactions with facility infrastructure (PV panels, etc.) or whether some of the fatalities might be unrelated to the presence of the facility. Mortality at these two Project sites was not unlike the estimates of background mortality observed on nearby reference sites. Given the low density of carcasses found within the solar arrays (<0.2/acre/year), a large field effort would likely be required to characterize background mortality with reasonable levels of precision if background rates were similar to the rates in the arrays.

In addition to issues associated with background mortality, multiple feather spots found on site may be from the same detection. Game cameras trained on carcasses for carcass persistence trials at the Project have documented the potential for multiple feather spots originating from a single trial carcass. Ravens and turkey vultures, and possibly roadrunners, dislodge feathers from their attachment to the skin of the carcass during the scavenging process. There are a very large number of potential feather spots present from a single bird carcass. This large number occurs because a feather spot is defined as at least two or more primary flight feathers, at least five or more tail feathers, or two primaries within five m (16.4 ft) or less of each other, or a total of 10 or more feathers of any type concentrated together in an area of three square m. Thus, the presence of feather spots among the detections for the Project would inflate the fatality estimate based on the potential for multiple feather spots, resulting from one fatality being counted as separate detections if feathers are either blown around the site, scattered by predators (e.g., plucking by ravens), resulting from predation not associated with the facility, or resulting from other unrelated causes. Nonetheless, feather spots are included in the analysis here to provide a more conservative estimate of fatality. If feather spots were excluded from the analysis, the overall estimates would be reduced by approximately 25%.

4.4 Fatality Estimates

The estimated density of carcasses for the Project components within the fence (solar arrays and fence) is only 0.15 carcasses/acre/year. More carcasses were estimated for the gen-tie than the solar arrays; however, the estimates for the gen-tie are unreliable due to very high carcass removal rates along that Project component. Approximately 270 water-associated carcasses (or 0.06 per acre) were estimated for the solar arrays.

EXECUTIVE SUMMARY

Avian and bat monitoring surveys were conducted from March 1, 2015 to February 28, 2016 (the 2015 – 2016 monitoring year) at Desert Sunlight Solar Farm Project (Project) in accordance with the Project's Bird and Bat Conservation Strategy (BBCS). Specifically, standardized carcass searches, searcher efficiency trials, and carcass persistence trials were conducted. This report represents the comprehensive annual report for the first year of monitoring, and summarizes monitoring methods and results for those surveys based on the procedures and requirements specified in the BBCS.

Standardized carcass searches were conducted 1) in the solar field, consisting of a random stratified 29.5% sample of solar photovoltaic (PV) panels, 2) along inner portions of the fenceline, resulting in 74.4% of the length of the perimeter fence, and 3) along 47.9% of the total length of generation-tie (gen-tie) line from the Project fence to the Red Bluff Substation located south of Interstate 10 (I-10). Searches were conducted at intervals of approximately seven days during spring and fall and 21 days during summer and winter.

All bird and bat fatalities and injuries that were discovered by observers, referred to as "detections" in this report, including those found incidentally and during standardized carcass searches, were documented. During the reporting period, 149 avian detections (including all stranded and injured birds and incidental detections), of 19 guilds and including 53 identified species, were made. The most numerous detection of an identified species was of American coot (*Fulica americana*) with 12 detections, followed by mourning dove (*Zenaida macroura*; n = 6). The most numerous detection in the solar arrays was American coot (n = 9), followed by western grebe (*Aechmophorus occidentalis*; n = 5) with no other species with more than four detections. The only species observed along the fence were American coot (n = 1), common raven (*Corvus corax*; n = 1), common loon (*Gavia immer*; n = 1), white-winged dove (*Zenaida asiatica*; n = 1), and mallard (*Anas platyrhynchos*; n = 1). Eurasian collared-dove (*Streptopelia decaocto*; n = 4) and orange-crowned warbler (*Oreothlypis celata*; n = 3) were the species with the most detections along the gen-tie/road. No bats were detected during the 2015 – 2016 monitoring year.

Avian detections were categorized by likely diurnal or nocturnal migration behavior, ecological guild (e.g., raptors, songbirds, etc.), facility component, and suspected cause of death. These standardized carcass search results, along with searcher efficiency and carcass persistence rates from bias trials conducted on site, were applied to a fatality estimator model (Huso 2010) to provide an estimate of the number of fatalities that occurred at the Project during the reporting period adjusted for sources of bias.

Mean (median) removal time within the solar field was 4.9 (6.0) days during spring, 12.7 (12.6) during summer, 2.5 (1.5) during fall, and 6.5 (6.0) during winter for small carcasses; 36.0 (27.8) days during spring, 36.0 (24.3) during summer, 12.2 (18.0) during fall, and 12.2 (6.8) during winter for medium carcasses; and 58.3 (31.0) days during spring, 13.7 (30.0) during summer,

58.3 (30.0) during fall, and 13.7 (5.1) during winter. At the overhead lines, removal time was 0.8 (0.5), 0.8 (0.5), 0.4 (0.5), and 2.3 (2.5) during spring, summer, fall, and winter respectively. For medium birds, mean (median) removal time at the overhead lines was 14.4 (2.0), 14.4 (15.8), 4.9 (1.5), and 4.9 (2.5) days during spring, summer, fall, and winter respectively. Mean (median) removal time for large birds was 5.8 (19.0), 1.4 (0.5), 5.8 (3.5), and 1.4 (3.5) days during spring, summer, fall, and winter respectively.

Within the solar arrays, searcher efficiency for small birds was influenced by cobble cover and season: small birds in high cobble cover in the fall had a searcher efficiency of 33.2% (CI: 13.3 – 63.9%; n = 15) and small birds in low cobble cover in the fall had a searcher efficiency of 57.8% (CI: 39.0 – 77.7%; n = 27). Searcher efficiency for small birds in high cobble cover during winter, spring and summer was 36.0% (CI: 21.1 – 45.4%; n = 50), and small birds in low cobble cover during winter, spring and summer had a searcher efficiency of 64.5% (CI: 44.5 – 63.4%; n = 70). For medium birds, searcher efficiency within the solar arrays was similar across cobble cover classes but differed by season: in winter, medium bird searcher efficiency was 93.5% (CI: 87.5 – 98.5%; n = 45), and in spring, summer and fall medium bird searcher efficiency was 83.2% (CI: 76.5 – 89.8%; n = 63). For large birds, searcher efficiency among the solar arrays differed between migration seasons (spring and fall) and non-migration seasons (summer and winter). Searcher efficiency during spring and fall for large birds was 83.9% (CI: 72.0 – 94.3%; n = 31). Searcher efficiency for large birds during summer and winter was 100% with no variance (n = 35). Sample sizes refer to numbers of trial carcasses that were available to be found, not numbers of trial carcasses that were placed.

For the fence, the model that included an effect of carcass size, and season (with spring and winter data lumped and summer and fall data lumped) was chosen as the most supported model to estimate searcher efficiency. Along the fence, searcher efficiency was 65% (CI: 52 – 77%), 94% (CI: 88 - 100%), and 100% (CI: 100 - 100%), for small, medium, and large carcasses, respectively during spring and winter and 87% (CI: 77 – 97%), 98% (CI: 96 – 100%), and 100% (CI: 100 – 100%) for small, medium, and large carcasses respectively during summer and fall.

For the gen-tie line, the chosen model included main effects of size, season (with spring and summer data lumped and fall and winter data lumped), and visibility class, with an interaction between visibility class and season. It ranked second by AICc, but was only 0.59 AICc points from the top model. It was chosen because it has similar predictive performance as the top model, but with fewer parameters to estimate. For the easy visibility class, searcher efficiency was 67% (CI: 53 – 81%), 89% (CI: 80 – 95%), and 89% (CI: 80 – 96%) for small, medium, and large carcasses, respectively during spring and summer and 57% (CI:46 – 68%), 84% (CI: 75 – 91%), and 85% (CI: 73 – 93%) for small, medium, and large birds respectively during fall and winter (Table 12). For the difficult visibility class, searcher efficiency was 75% (CI: 62 – 86%), 92% (CI: 86 – 97%), and 92% (CI: 84 – 97%) for small, medium, and large birds respectively during spring and summer and 33% (CI: 22 – 44%), 65% (CI: 53 – 77%), and 67% (CI: 51 – 82 %) for small, medium, and large birds respectively during fall and winter.

Using the Huso (2010) fatality estimator model, during the 2015 – 2016 monitoring year, there were an estimated 1,328 bird carcasses (CI: 1,007 – 2,303) at the Project (all components combined). There were an estimated 53 (CI: 28 – 85) large birds, 336 (CI: 246 – 449) medium birds, 881 (CI: 566 – 1,843) small birds, and 58 (CI: 22 – 143) birds of unknown size at the Project (all components combined).

There were an estimated 628 (CI: 496 – 951) bird carcasses (152/1000 acres, 1.16/nameplateMW) at the solar arrays, 11 (CI: 2 – 26) at the fence, and 688 (CI: 364 – 1,567) along the gen-tie line. Estimates of fatalities along the gen-tie are heavily influenced by the high rates of scavenging observed during the limited trials at the gen-tie (i.e., large correction factors) and are likely very unreliable.

1 INTRODUCTION

1.1 Project Background

Desert Sunlight 250, LLC and Desert Sunlight 300, LLC (collectively, Desert Sunlight) constructed and operates the Desert Sunlight Solar Farm Project (Project), which consists of two main components: 1) a 550-megawatt (MW) photovoltaic (PV) generating facility; and 2) a 220-kilovolt generation interconnection (gen-tie) line. The Project comprises approximately 1,700 hectares (ha; 4,200 acres) of land administered by the Bureau of Land Management (BLM) six miles north of Desert Center in Riverside County, California (Figure 1).

1.2 Monitoring Plan Overview and Goals

A Bird and Bat Conservation Strategy (BBCS; 2014) was prepared by the Project proponent in collaboration with the US Fish and Wildlife Service (USFWS), California Department of Fish and Wildlife (CDFW), and BLM to guide comprehensive monitoring of impacts to birds and bats associated with operation of the Project. Final agency approval of the BBCS occurred in December 2014. Amendments to the sampling protocol along some portions of the Project fenceline were made by Desert Sunlight and approved by the BLM on February 11, 2015.

The BBCS details post-construction monitoring to be conducted and the data analysis and reporting processes that will be implemented by Desert Sunlight in collaboration with the USFWS, CDFW, and BLM. As identified in the BBCS, they are:

1. Estimate overall annual avian fatality rate and species composition associated with the Project infrastructure. This estimate will include mortality associated with solar arrays, overhead lines including the gen-tie line, perimeter fence and other features of the Project that may result in injury and fatality.

2. Determine whether there are spatial and temporal/seasonal patterns of mortality associated with Project infrastructure (e.g., different fatality rates near panels on the edge of the arrays vs. the interior area of the arrays).
3. Provide information that will assist the BLM in consultation with the USFWS in understanding which species and potentially which regional populations are at risk.
4. Collect data in such a way that the BLM in consultation with the USFWS may make comparisons with other solar sites.

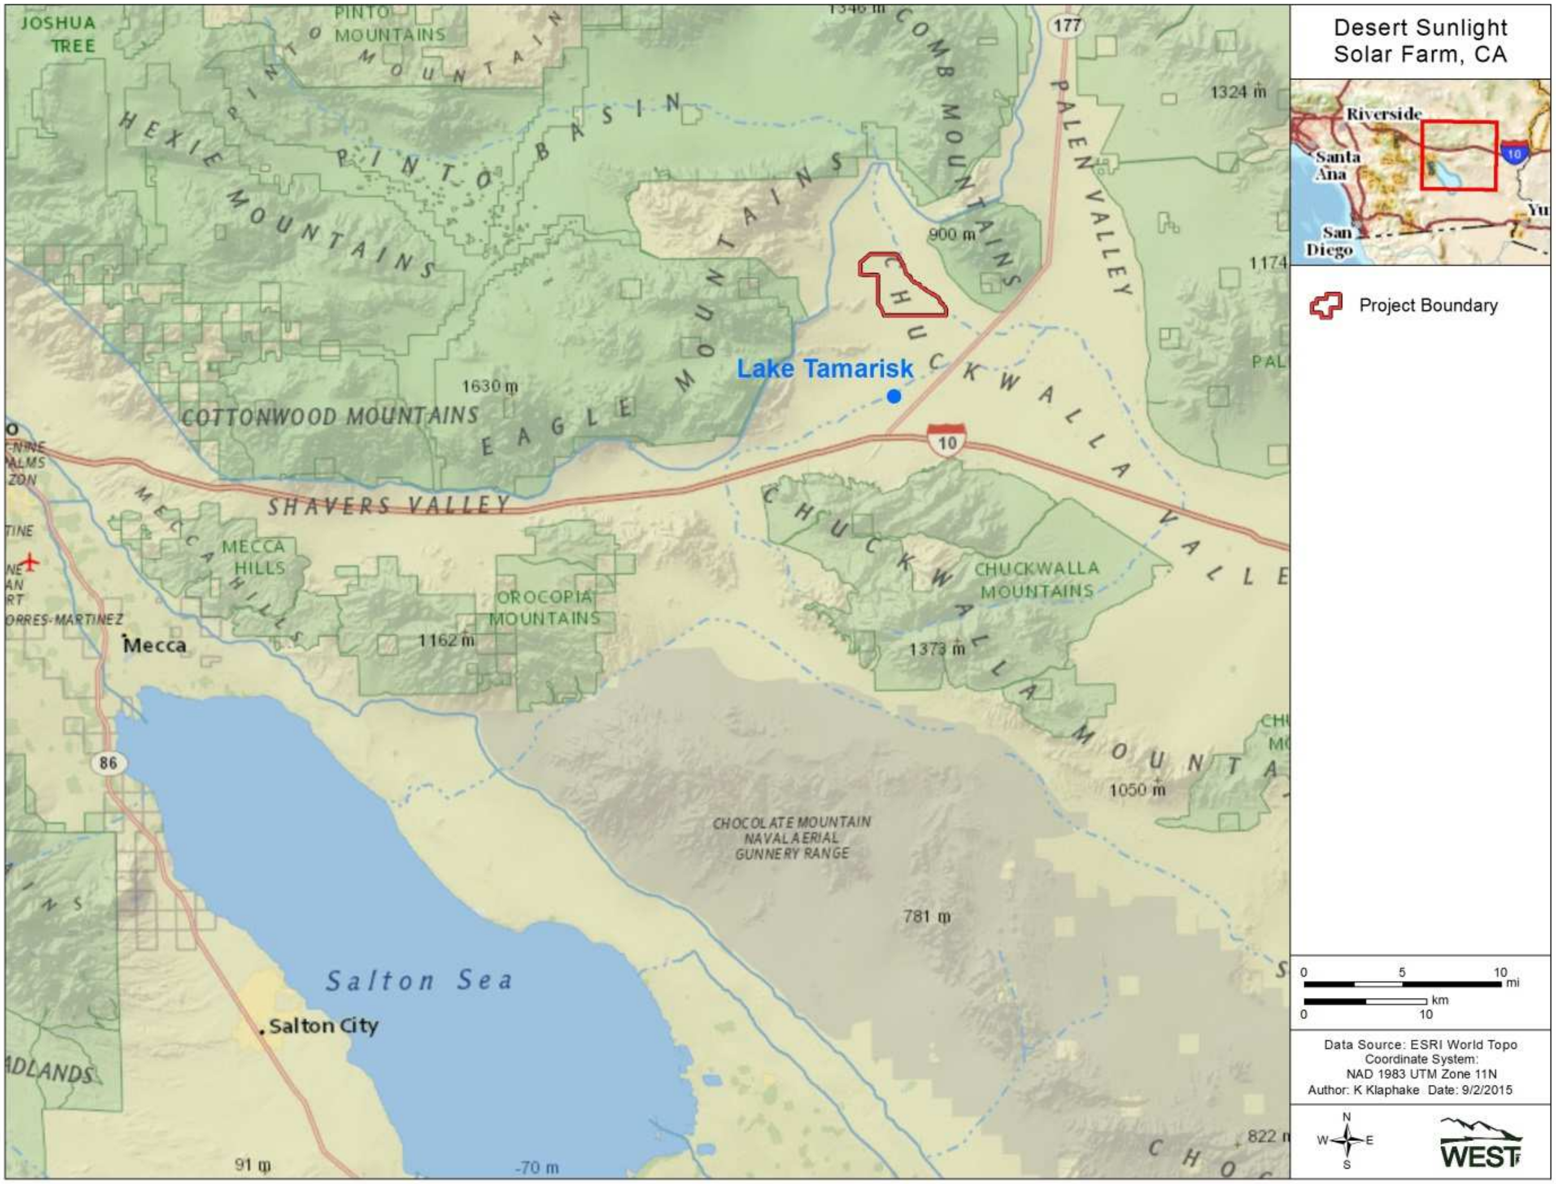

Figure 1. Desert Sunlight Solar Farm Project vicinity map, Riverside County, California.

1.3 Purpose of This Report

This report represents the comprehensive annual report for the first year of monitoring summarizing monitoring methods and results for avian and bat fatalities and injuries based on the procedures and requirements specified in the approved BBCS. This report includes data and final information from all four quarterly monitoring periods.

This report covers the 2015 – 2016 monitoring year, which includes the period from March 1, 2015 to February 28, 2016. All carcasses and injuries that were discovered by observers are referred to as "detections" in this report. As stated in the approved BBCS, this report includes the observed detections for likely diurnal, and likely nocturnal species, and for ecological guilds of interest (e.g., raptors, water-associated birds, passerines), for each of the facility types and for suspected causes of death. Species composition of detections and the results of the bias trials are also included in this report.

2 METHODS

The following section describes the field and statistical methods used during the monitoring period, including the analytical methods for estimating overall avian fatality rates.

2.1 Standardized Carcass Searches

This section describes areas surveyed, the timing and frequency of searches, and the methods by which standardized searches were conducted to identify dead/injured birds and bats at the Project. This section also describes the methods for conducting carcass removal and searcher efficiency trials; the methods for reporting and analyzing data, and the methods for producing fatality estimates for the Project.

2.1.1 Areas Surveyed

Standardized carcass searches were conducted at sampling units, which include the solar arrays (Table 1, 2; Figure 2); the "fenceline" defined as the perimeter fence for the Project (Table 1, Figure 2); and the gen-tie line (from the Project fence to the Red Bluff Substation on the south side of I-10; Table 1, Figure 3). Some overhead lines co-occur with solar arrays (medium voltage overhead (MVOH) lines). The MVOH lines were part of standardized carcass searches to the extent that they co-occurred with solar arrays included in the sample (Table 2; Figure 2).

Table 1. Areas included in standardized carcass searches at the Desert Sunlight Solar Farm Project during the 2015 – 2016 monitoring year (March 1, 2015 – February 28, 2016).

Project Component	Total Size	Units	% of Component Searched
Solar arrays	1045.9	Hectares	30.0[1]
Fence	16.7	Kilometers	99.0[2]
Gen-tie line	19.2	Kilometers	47.9[3]

[1] Percent area that was searched in spring (28.2) summer (29.5), fall (29.5), and winter (29.5), slightly less than 30% total because of unequally sized arrays.

[2] 74.4% of the fence is fully accessible and surveyed following the standard protocol, while approximately 25% of the fence is surveyed from a distance. Fatality rates estimated for sections of the fence that are sampled were extrapolated to sections of the fence where the standard monitoring protocol cannot be used, as described in Section 4.2.6 of the approved Desert Sunlight BBCS. A very short segment near the gate is not sampled due to restoration activities.

[3] 52.1% of the gen-tie will be sampled in 2016.

Table 2. Area and proportion of solar arrays that are and are not associated with overhead lines at the Desert Sunlight Solar Farm Project, Riverside County, CA.

	Line-associated[1]	Not line-associated	Proportion line-associated
Entire facility	89.4 ha	956.5 ha	0.09
Standardized searches	32.2 ha	291.0 ha	0.10

[1] Line-associated area was estimated as the area of any array that fell within the 30-m strip transect below the MVOH line.

Note: Hectares (ha)

To ensure a balanced distribution of sample units in the solar field (defined as the collection of all PV solar panels), the entire field was divided into ten strata, and individual sampling units were randomly selected within each stratum to compose an approximately 30% sample. This sampling design ensures that units included in the sample were not spatially clumped within the solar field. The solar field consists of arrays of solar panels (referred to as a solar array) that are either 70 meters (m) or 140-m wide. The sample includes 133 of each type of array. There are 2,580 70-m rows, and 3,900 140-m rows in the sample.

On April 21, 2015, the Project was struck by a tornado. The tornado damaged some of the sampling units and resulted in limited access that ultimately lasted longer than initially expected. Thus, 142 sample units (128 arrays, fence, and gen-tie combined) were visited 12 times continuously and without interruption during the spring season. Six arrays were visited seven times from the beginning of the spring season until the tornado occurred on April 21, 2015; three weeks elapsed before the six damaged arrays were replaced with arrays in the solar field that were not affected by the tornado. During this three week period, Desert Sunlight LLC remained in contact with the BLM as details on access limitation developed. Once it was determined that access to damaged arrays would be limited for a longer time period, six replacement arrays were identified by choosing a random sample of non-damaged arrays within the same block that contained the original arrays that were damaged by the tornado.

2.1.2 Search Frequency and Timing

Standardized searches occurred during the 2015 – 2016 monitoring year, which includes the period from March 1, 2015 through February 28, 2016. All Project components included in standardized searches were surveyed 31 times during the 2015 – 2016 monitoring year (12 times during spring, four times during summer, nine times during fall, and six times during winter). All searches took place during daylight hours from 06:30 to 17:00.

The average search interval for all Project components included in standardized carcass searches was 7.0 (median 7.0) during spring, 22.8 days (median 21.0 days) during summer, 8.1 days (median 7.0 days) during fall, and 19.1 days (median 21.0 days) during winter. Slight variation in search interval was anticipated due to weather and logistical delays.

2.1.3 Search Methods

Standardized carcass searches were performed by BLM-approved biologists in accordance with methods outlined in the BBCS.

Within the solar field, arrays of solar panels were surveyed by observers traveling on foot. A distance sampling approach was used whereby biologists slowly walked a transect line along the ends of rows of solar panels in a direction perpendicular to the rows, searching ahead and to the side within the array for bird and bat detections. Biologists scanned out to a maximum perpendicular distance of approximately 70 m from the transect. Biologists carried binoculars to allow them to verify the presence of a detection as opposed to rocks or vegetation. Once a detection was confirmed, the distance of the detection to the transect line was estimated using laser range finders. Each array included in the sample was searched by observers walking two transects – one on the west side and one on the east side of the array with observers looking toward the center of the array.

Once a carcass was detected, it was photographed, and data were recorded according to specifications outlined in Section 7.2.5 of the approved Desert Sunlight BBCS. Carcasses were then retrieved from their location on the ground, labeled, and placed in a freezer on site.

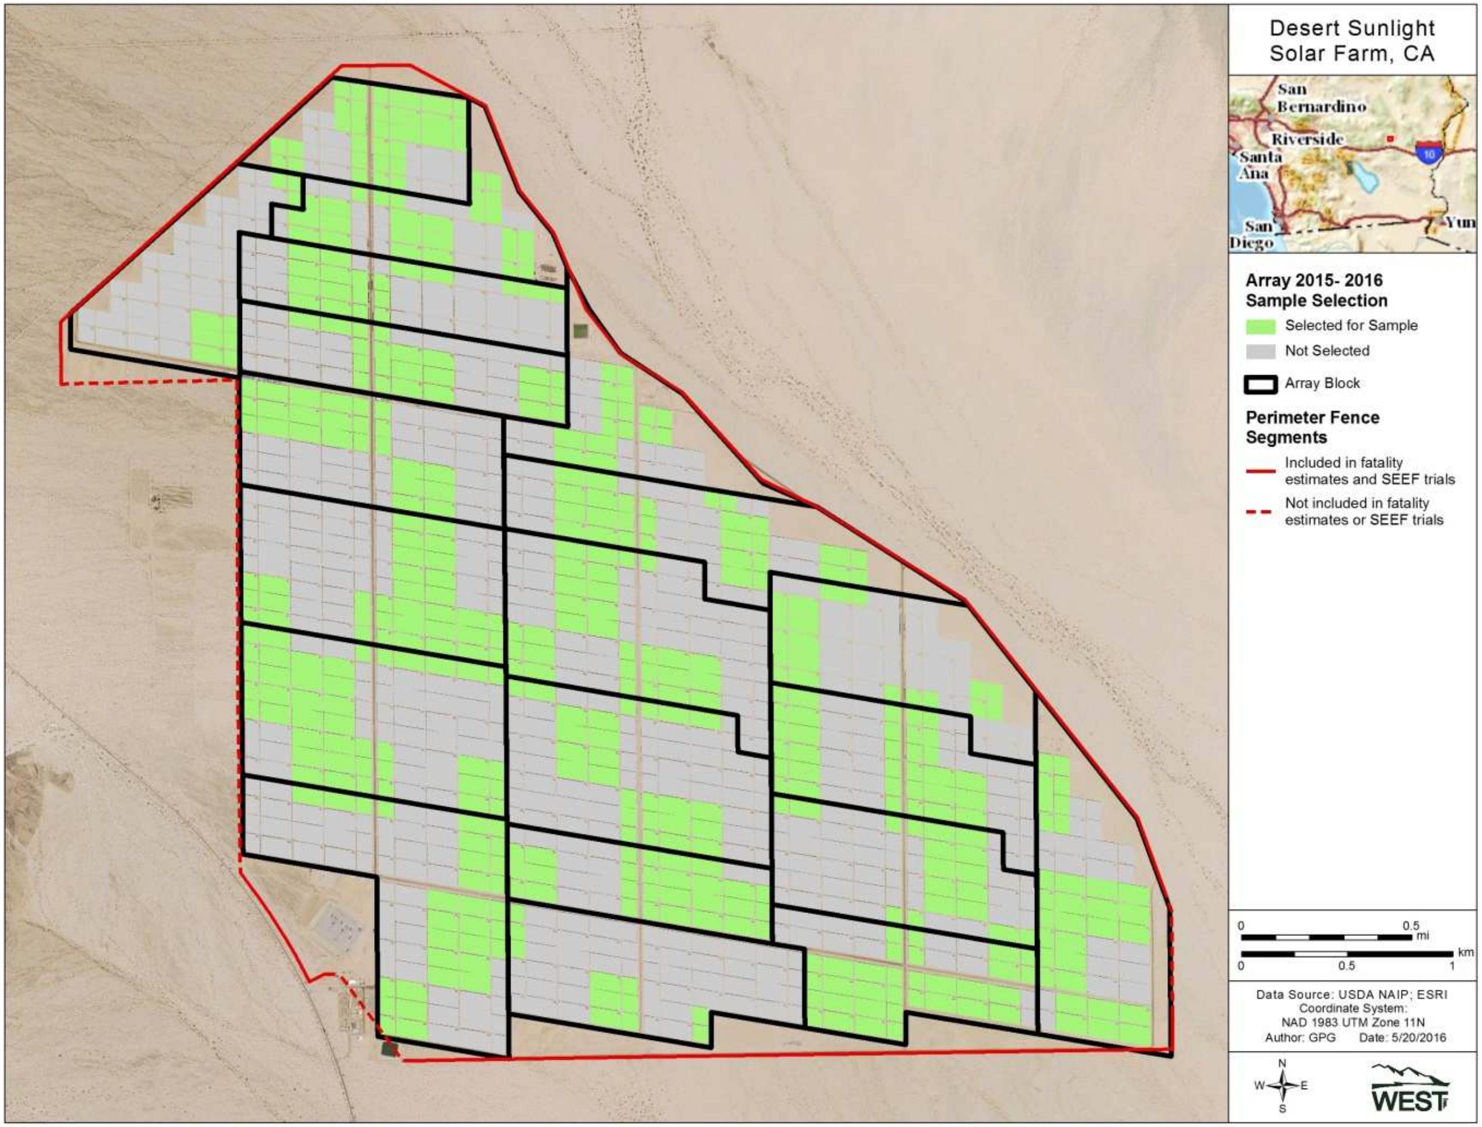

Figure 2. Areas of standardized searches at the solar field, visitor center, and overhead lines within the fence at Desert Sunlight Solar Farm Project during the 2015 – 2016 monitoring year (March 1, 2015 – February 28, 2016).

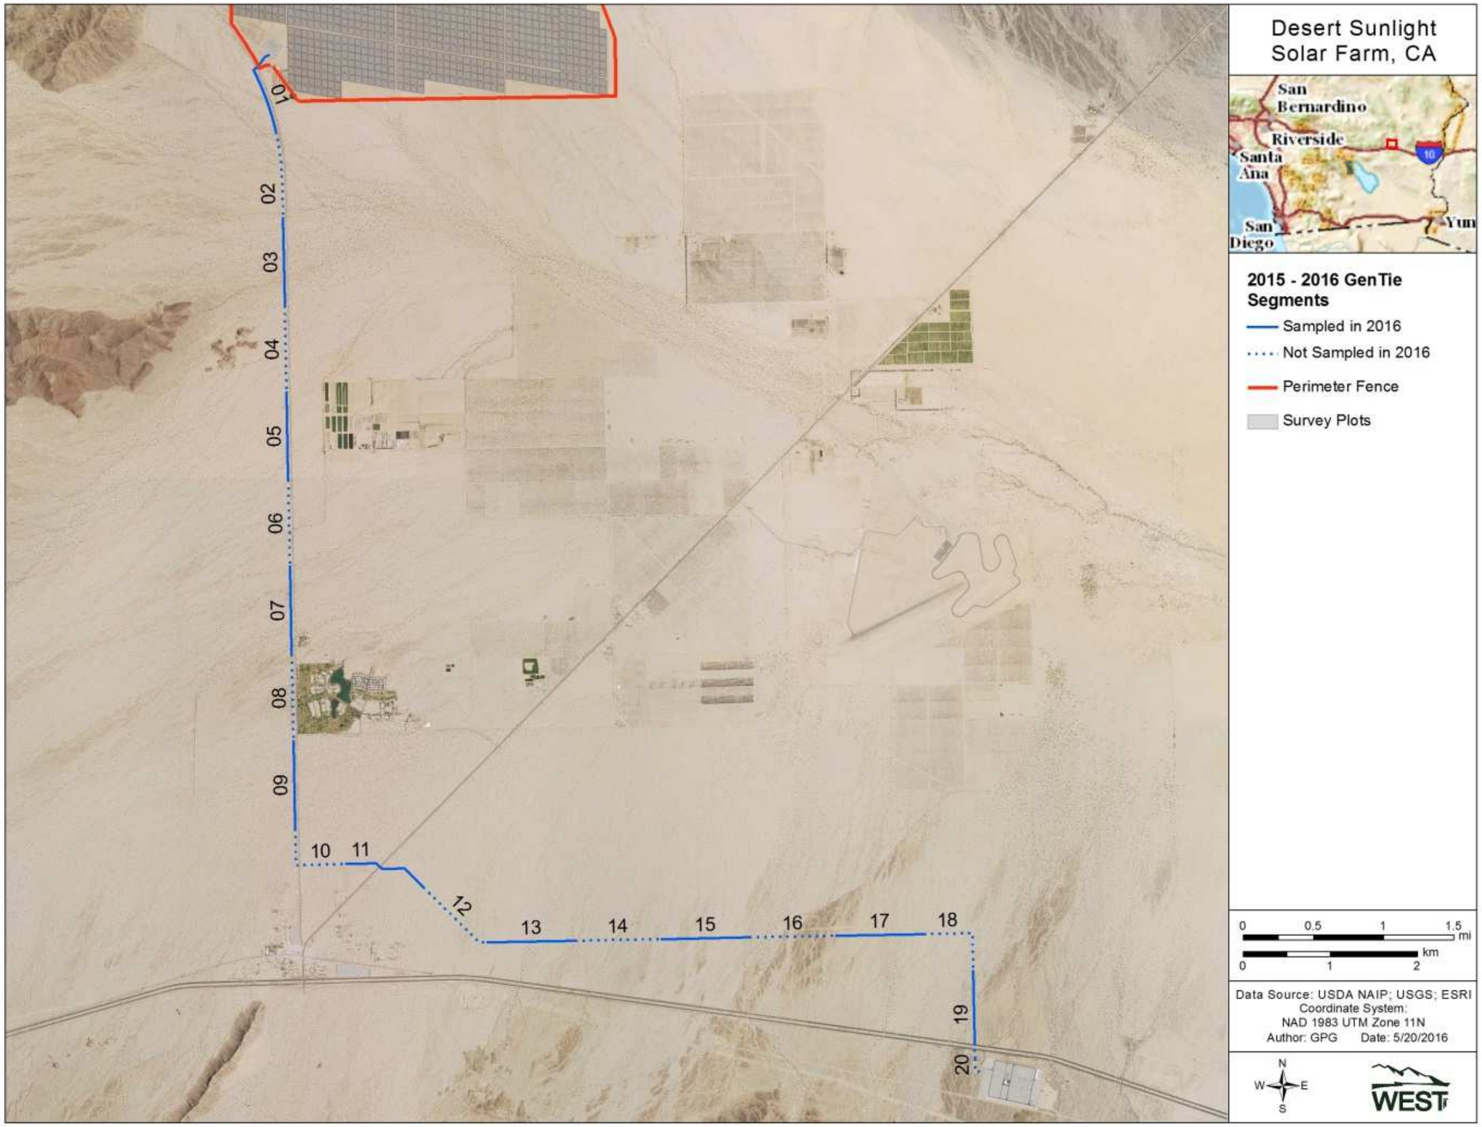

Figure 3. Areas of standardized searches along the generation tie line at Desert Sunlight Solar Farm Project during the 2015 – 2016 monitoring year (March 1, 2015 – February 28, 2016).

Most (74.4%) of the length of fenceline (approximately 10 miles; Figure 2) was searched from a vehicle using the standard protocol. Biologists searched a 6-m wide strip transect centered on the fence from the inner perimeter. Travel speed was below five miles per hour (mph) while searching. Some sections along the fence cannot be driven close to the fence line. The fence line along the western edge of the Project is drivable but the road is approximately 15 m away from the fence and the road and fence are separated by a drainage ditch. The fence along this section is covered with a tan tarp and trees and shrubs have been planted to reduce visibility of the Project from the west. Additions of vegetation and the tarp likely reduce potential for bird collision with the fence. This section of the fence was driven to document carcasses, but detections along this portion of the fence are not included in adjusted fatality estimates because detection rates are likely very low. As specified in Section 4.2.6 in the approved Desert Sunlight BBCS, we assume that fatality rates are similar between the portion of fence that was searched and the portion that was not. A separate section of the fence in the southeastern corner of the Project cannot be driven because the eastern edge of the berm that bounded construction ponds is too narrow for a vehicle. Along this portion of the fence, the observer stopped at both north and south ends of the berm and used binoculars to search for carcasses. Finally, the area along a portion of the southwest fence line near the entrance gate is approximately 30 to 50 m from the road and is separated from the fence by an area that has recently undergone vegetation restoration. This area was also eliminated from sampling. Fatality rates estimated for sections of the fence that were sampled were adjusted to account for the proportion of fence not sampled with the standard monitoring protocol, as specified in section 4.2.6 of the approved Desert Sunlight BBCS. In other words, the fatality rates (number of carcasses/m of fenceline sampled) was multiplied by the total fenceline in the facility to get the total fenceline carcass estimate for the facility.

The gen-tie line was searched using a 30-m wide strip transect (i.e., 15 m of ground on either side of the overhead line). Sample units along the gen-tie line were chosen by dividing the total length of line from the Project fence south to the Red Bluff Substation just south of I-10 into 1-kilometer (km) segments. Thus, a 47.9% sample of the total length of the line was searched (Figure 3). Biologists slowly walked every other 1-km segment of the line, meandering the width of the strip transect, scanning for dead or injured birds or bats within 15 m (49.2 feet [ft]) of the overhead line.

For each detection, a suspected cause of death or injury was assigned based on evidence available from the detection, evidence available on Project infrastructure, and proximity of the detection to Project infrastructure. Detections that had evidence of scavenging and lacked evidence on Project infrastructure were assigned “unknown” cause of death because it cannot be determined whether the event was caused by predation or interaction with Project infrastructure. Detections that were intact (i.e., no evidence of scavenging) and located in close proximity to Project infrastructure (e.g., found directly beneath overhead lines) had a suspected cause of death attributed to the respective Project component. However, it should be noted that there is substantial uncertainty associated with cause of death assignments because no events were directly observed. Detections assigned to the “unknown” category were included in fatality estimates if they were located within standardized carcass search areas, and all detections made during the 2015 – 2016 monitoring year are reported here.

2.2 Carcass Persistence Trials

Carcass persistence trials were conducted in each of the four seasons during the 2015 – 2016 monitoring year. Carcasses from three size classes were used for trials (small: zero-100 grams [g], medium: 101-999 g, and large: 1000+ g). The small size class comprised house sparrows (*Passer domesticus*) and 2-3 week old coturnix quails (*Coturnix coturnix*), the medium size class comprised rock pigeons (*Columba livia*), chukar (*Alectoris chukar*) and adult coturnix quail, and the large size class comprised of hen mallards (*Anas platyrhynchos*) and hen ring-necked pheasants (*Phasianus colchicus*).

2.2.1 Carcass Persistence Data Collection

To quantify carcass persistence rates, 15 small, 10 medium, and 5 large carcasses were randomly placed and monitored along the gen-tie line during each seasonal monitoring period. Within the solar arrays the same numbers of each size category were placed at Desert Sunlight, as specified in the approved Desert Sunlight BBCS. During spring, an additional five large bird carcasses were placed within the solar arrays. During winter, an additional five large birds (two along the gen-tie and three within the solar arrays), 10 medium birds (five along the gen-tie and five within the solar arrays), and 15 small birds (eight along the gen-tie and seven within the solar arrays) were placed. Thus, 275 carcasses were placed during the 2015 – 2016 monitoring year. By placing carcasses inside (within arrays and along inner perimeter of the fence) and outside (along the gen-tie) the Project fence, the possibility of different carcass persistence rates inside and outside the Project fence is accounted for. During the 2015 – 2016 monitoring year, 70 carcasses (13 during spring, 15 during summer, 15 during fall, and 27 during winter) within the Project fence (within solar arrays and along the fence) were monitored using motion-triggered digital trail cameras as well as by visits on foot. The remaining carcasses were visited on foot for 30 days or until the carcass had deteriorated to a condition at which it would no longer qualify as a documentable fatality. No carcasses along the gen-tie line were monitored with cameras because of theft and vandalism concerns. Carcasses without trail cameras were visited and photographed once per day for the first four days, and then every three to five days until the end of the monitoring period. To avoid training scavengers to recognize cameras as "feeding stations," trail cameras were installed five days before specimens were placed. In addition, two fake cameras (four cameras used during spring) were placed within the Project fence in areas without bias trial carcasses and periodically moved to new locations within the fence. Periodic ground-based checking of carcasses with trail cameras also occurred to guard against misleading indicators of carcass removal, such as wind blowing the carcass out of the camera's field of view. To minimize potential bias caused by scavenger swamping (Smallwood 2007, Smallwood et al. 2010), carcass-persistence specimens were distributed across the entire Project, not just in areas subject to standard searches, and trials were initiated in smaller numbers on two to three different dates throughout each of the four seasonal monitoring periods.

2.2.2 Estimating Carcass Persistence Times

Measurements of carcass persistence rates were subject to censoring. In this context, censoring refers to the instance when a value (e.g., days a carcass is present before being removed) may not be exactly known, but is known to be within a finite range. For example, suppose a carcass was checked on day seven and was present, and was checked again on day ten, but was found to be missing. The exact time until removal is unknown; however, it is known that the carcass became unavailable at some point between seven and ten days. This carcass would be considered “interval censored”. Similarly, if a carcass lasts the entire 30-day trial period, that carcass is “right censored”— it is known that the carcass lasted at least 30 days, but it may have persisted longer. Because carcass persistence data was censored, persistence was analyzed using methods that can accommodate censored data and still produce unbiased estimates of the probability of persistence (Therneau 2015, Therneau and Grambsch 2000). It is beyond the scope of this document to provide statistical foundations of censored-data survival models, but functions identical to those provided with the USGS-developed fatality estimator software (Huso et al 2012) were used to fit survival models to the censored carcass persistence data, and some background is available in the documentation provided with that software.

USGS-developed fatality estimator software (Huso et al 2012) was used to fit survival models to the censored carcass persistence data. The USGS software used to estimate carcass persistence calculates the period over which there is less than a 1% chance for a carcass to persist. The 'effective search interval' is defined as the shorter of a) the length of time beyond which there is less than a 1% probability that a carcass persists, and b) the actual search interval (Huso 2010). The probability of persistence is given for the effective search interval, and the probability that a carcass persists through the actual search interval is equal to *p* (persist through effective search interval) * effective search interval / actual search interval.

There were four distributions implemented in survival models used to estimate the probability a carcass is un-scavenged and available to be found at the end of the search interval (*r)*: exponential, Weibull, loglogistic, and lognormal. These four distributions exhibit varying degrees of flexibility in order to model a wide variety of distributions of persistence time. Akaike’s Information Criterion corrected for sample size (AICc; Akaike 1973) was used to rank the fit of each survival model with combinations of the covariates carcass size, Project component, season, and visibility, to observed carcass persistence data.

2.3 Searcher Efficiency Trials

Searcher efficiency trials were conducted throughout the 2015 – 2016 monitoring year. Carcasses from three size classes (small, medium, and large) were used for trials. The small size class comprised house sparrows and two- to three-week-old coturnix quails, the medium size class comprised rock pigeons, chukars, and older coturnix quails, and the large size class comprised hen mallards and hen ring-necked pheasants.

2.3.1 Searcher Efficiency Data Collection

Training of biologists on the Project-specific protocol and early assessments of habitat conditions within the solar arrays suggested that the amount of cobble present in the soil may be an important factor influencing searcher efficiency. To satisfy requirements regarding consideration of visibility class per the BBCS and address the influence of cobble cover on searcher efficiency, sample units in the solar arrays and along the gen-tie were stratified by cobble cover and assigned to one of two classes (<15% and >15% cobble cover). Classes were determined by making ocular estimates of cobble cover at each sample unit and then evaluating the frequency histogram of sample units across the range of estimated cobble cover (Figure 4). A natural break point was identified at 15% cobble cover, so the same value was chosen as the break point that defined the two cobble cover classes. The high cobble class made up only 13% of the sample units. Thus, in the solar arrays, two sets of searcher efficiency trials were conducted during the 2015 – 2016 monitoring year (one set in each cobble cover class; *n* in low cobble equals 110 small birds, 71 medium birds, and 41 large birds; *n* in high cobble equals 71 small birds, 42 medium birds and 25 large birds [see Table 3 for placement by size, visibility class, and Project component for each season]). Along the gen-tie, visibility was expected to be related to vegetation and rock cover. Thus, searcher efficiency trials along the gen-tie occurred in two visibility classes (easy: ≥90% bare ground, vegetation <6" tall; and more difficult: <90% bare ground, vegetation ≥6" tall). Sample sizes for the easy class and the more difficult class were 75 small birds, 50 medium birds, and 27 large birds and 76 small birds, 50 medium birds, and 27 large birds respectively. The entire fence line was considered an easy visibility class. One hundred fifty searcher efficiency trials occurred along the fence (n = 75 small birds, 50 medium birds, 25 large birds). During the 2015 – 2016 monitoring year, 810 searcher efficiency trials occurred at the Project. Locations for trials were chosen by taking a randomized sample of all locations included in standardized carcass searches.

Table 3. Searcher Efficiency Placements by size, visibility class, and Project component for each of the four seasonal monitoring periods at the Desert Sunlight Solar Farm Project, Riverside County, California.

Project Component	Visibility Class	Size	Spring	Summer	Fall	Winter	Total
Solar Arrays	High	LB	4	0	6	15	25
Solar Arrays	High	MB	3	0	9	30	42
Solar Arrays	High	SB	11	0	15	45	71
Solar Arrays	Low	LB	12	10	9	10	41
Solar Arrays	Low	MB	10	20	21	20	71
Solar Arrays	Low	SB	20	30	30	30	110
Fence	Easy	LB	5	5	5	10	25
Fence	Easy	MB	10	10	10	20	50
Fence	Easy	SB	15	15	15	30	75
Gen-tie	Diff	LB	5	3	4	10	22
Gen-tie	Diff	MB	9	11	11	19	50
Gen-tie	Diff	SB	15	16	15	30	76
Gen-tie	Easy	LB	5	6	6	10	27
Gen-tie	Easy	MB	11	9	9	21	50
Gen-tie	Easy	SB	15	15	15	30	75
Season Totals			**150**	**150**	**180**	**330**	**810**

Large bird = (LB); Medium bird = (MB); Small bird = (SB). Low = low coble cover; High = high coble cover; Diff = difficult visibility class; Easy = easy visibility class.

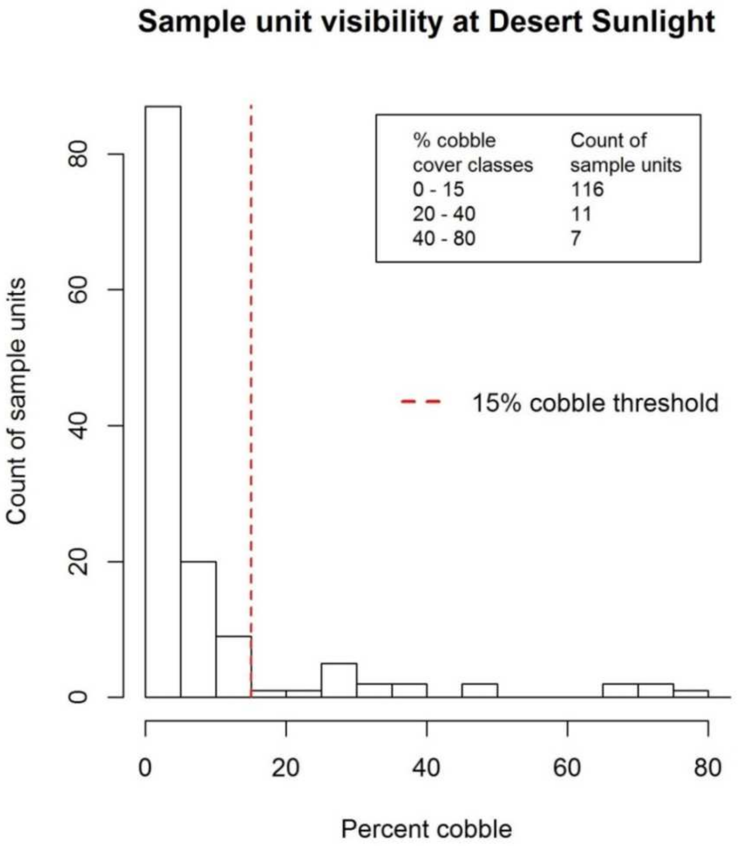

Figure 4. Frequency histogram of sample units (in the arrays only) at Desert Sunlight Solar Farm Project by estimates of cobble cover. Based on this distribution, each sample unit was assigned to one of two classes of cobble cover (<15%; >15%).

2.3.2 Estimating Searcher Efficiency

Searcher efficiency at Desert Sunlight was estimated separately for linear features (the Project fence and the gen-tie line), and the solar arrays, reflecting the different search methods used on arrays and linear features. For linear features, logistic regression models were fit to searcher efficiency data, and AICc was used to compare models. Models including effects of carcass size (three classes), visibility (two classes; gen-tie only), and season were compared to each other and the null (i.e., intercept only) model. Once the most supported model was chosen and appropriate classes identified, searcher efficiency, or the proportion of carcasses detected, *p*, was calculated for each class using the following equation:

$$p = \frac{Number\ of\ Carcasses\ Observed}{Number\ of\ Carcasses\ Available}$$

The data for this analysis included all searcher efficiency trial carcasses from the 2015 – 2016 monitoring year.

For the solar arrays, searcher efficiency was evaluated using a distance sampling approach (Buckland et al. 1993). Distance sampling assumes perfect detection on the transect line (at distance = 0), an assumption that is likely valid in the solar arrays given the relatively flat & vegetation-free nature of the soil surface. A curve is fitted to the observed carcass data that predicts probability of detection as a function of distance from the transect line. The mean value of this function over a specified distance, *w,* is equal to the average searcher efficiency for a transect of width *w*. The mean value of the detection curve is the integral of the detection function calculated between 0-m and the maximum survey distance (*w;* half the width of the solar array row), divided by the maximum survey distance:

$$p = \frac{\int_0^w f(x)dx}{w},$$

where f(x) is the detection function evaluated at distance, *x*.

One departure in the methods used here, relative to the methods presented in Buckland et al. (1993), was that for this study the detection function was estimated using trial carcasses, which meant that there were both presence (detected) and absence (not detected) data available to fit the detection function (Figure 5, 6, and 7). The availability of both presence and absence data means that the detection function can be estimated using only trial carcasses whose distribution is known. Therefore the detection function, the average searcher efficiency among the arrays, and the final fatality estimate within the arrays are all insensitive to the spatial distribution of carcasses within individual arrays, and the overall searcher efficiency estimate is valid even if the distribution of carcasses among the arrays is not uniform.

Distances of trial carcasses (trials both found and missed) from the transect line were used to fit half-normal, exponential, and hazard rate distribution detection functions for searches among the arrays, which are all commonly used functions for distance sampling surveys (Buckland et al. 1993). The fit of detection functions were compared using AICc and each model was fit with covariates season, carcass size, cobble cover class), and without. Model fits that indicated searcher efficiency increasing at greater distances (n = 54 of 312 candidate models) were excluded from consideration. Size classes were evaluated separately: small bird searcher efficiency was best described by a hazard rate detection function and a model that included cobble cover and split seasons into fall and spring/summer/winter (Figure 5). Medium bird searcher efficiency was best described using an exponential detection function and differed between winter and spring/summer/fall (Figure 6). Large bird searcher efficiency was best described using a uniform detection function and differed between spring/fall and summer/winter (Figure 7).

Because the solar arrays were surveyed by searchers who walked down both sides of the rows of panels, the width of the search transect was specified as half the width of the rows of panels. For larger birds, there is almost certainly a non-zero detection probability beyond this distance but the bias that occurs by ignoring this non-zero detection probability is conservative (i.e., the searcher efficiency is underestimated). Some solar arrays have row widths of 70 m (search transect width of 35 m) and some have row widths of 140 m (search transect width of 70 m). The weighted average searcher efficiency is calculated based on the number of panel rows of each length in the survey sample:

$$p_{weighted\ average} = \frac{n_{70}}{n} \times \frac{\int_0^{35} f(x)dx}{35} + \frac{n_{140}}{n} \times \frac{\int_0^{70} f(x)dx}{70},$$

where n_{70} is the number of 70-m rows in the sample, n_{140} is the number of 140-m rows in the sample, and *n* is the total number of rows in the sample. Searcher efficiency was higher for the arrays with a width of 70 m, and overall searcher efficiency was estimated as a weighted average based on the proportions of 70-m arrays and 140-m arrays in the sample units.

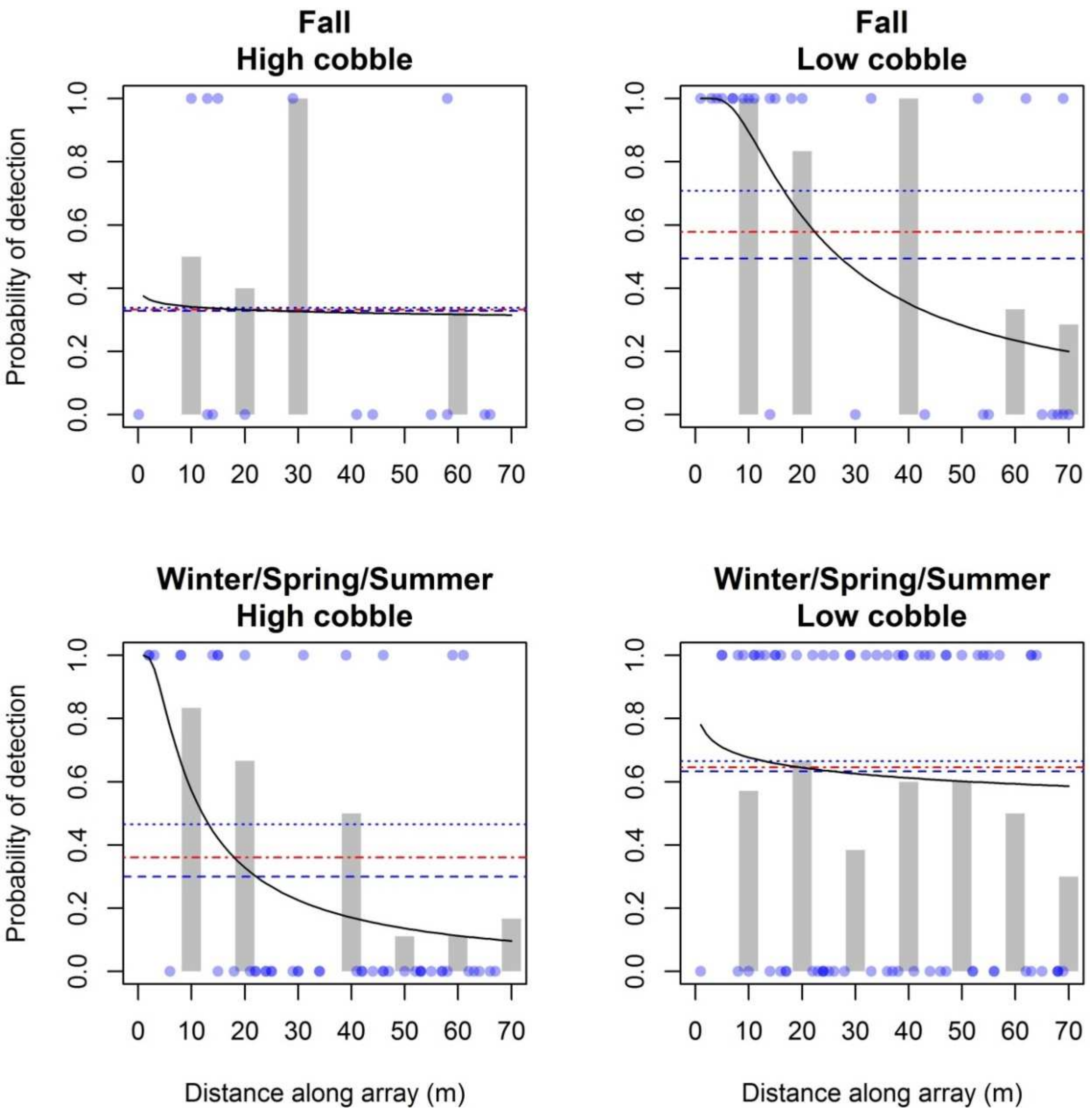

Figure 5. Estimated detection probabilities for small bird carcasses by cobble cover class and season during the 2015 – 2016 monitoring year (March 1, 2015 – February 28, 2016) at the Desert Sunlight Solar Farm Project, Riverside County, California. Distance sampling was used when searching solar arrays only. Average probability of detection over 70-m (arrays relying on a 35-m viewshed) and 140-m (arrays relying on a 70-m viewshed) panel rows in solar arrays are presented.

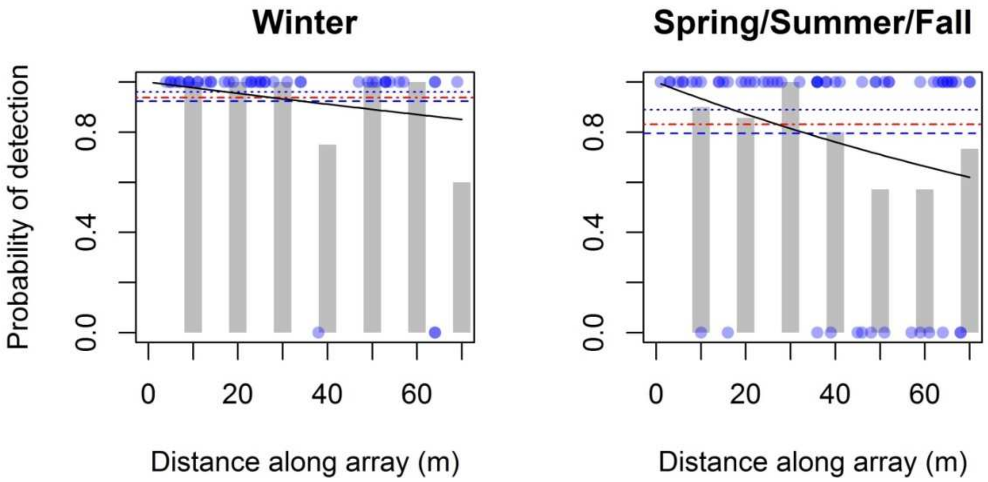

Figure 6. Estimated detection probabilities for medium bird carcasses by season during the 2015 – 2016 monitoring year (March 1, 2015 – February 28, 2016) at the Desert Sunlight Solar Farm Project, Riverside County, California. Distance sampling was used when searching solar arrays only. Average probability of detection over 70-m (arrays relying on a 35-m viewshed) and 140-m (arrays relying on a 70-m viewshed) panel rows in solar arrays are presented.

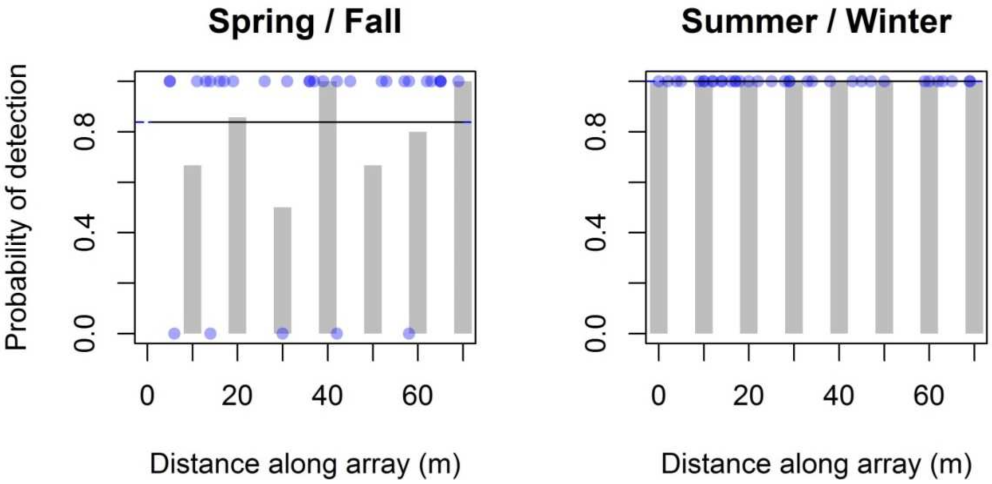

Figure 7. Estimated detection probabilities for large bird carcasses by season during the 2015 – 2016 monitoring year (March 1, 2015 – February 28, 2016) at the Desert Sunlight Solar Farm Project, Riverside County, California. Distance sampling was used when searching solar arrays only. Average probability of detection over 70-m (arrays relying on a 35-m viewshed) and 140-m (arrays relying on a 70-m viewshed) panel rows in solar arrays are presented.

2.4 Fatality Estimator

Fatality rate estimation is a complex task due to several variables inherent to every fatality monitoring study. Carcasses may persist for variable amounts of time due to local scavenger activity or environmental conditions leading to carcass degradation over time. Carcasses and feather spots were also detected with varying levels of success based on carcass characteristics and ground cover (e.g., vegetated areas underneath the gen-tie line versus cleared areas beneath solar panels). For these reasons, it is generally inappropriate to draw conclusions based on the raw number of fatalities alone. The desire to estimate fatalities given these variables has driven the development of several statistical methods for estimating fatalities (e.g., Smallwood 2007, Huso 2010, Korner-Nievergelt 2011). All of these fatality estimation methods share a similar underlying model. Generally, the fatality estimation for a given site may be written as:

$$F=C/rp,$$

where F is the total number of fatalities, C is the number fatalities detected and included in fatality estimation, r is the probability a carcass is un-scavenged and available to be found at the end of the search interval, and p is the probability of detecting a carcass (Huso 2010). Huso (2010) describes the use of a binomial model to estimate the probability of carcass detection in the present study. The binomial carcass detection model was used to calculate fatalities at Project linear features (fence, overhead lines) and the weighted average probability of detection based on distance sampling (described above) was used to estimate probability of detection within the solar arrays.

All fatality estimates were calculated using the Huso estimator (modified to accommodate the distance-sampling based estimate of searcher efficiency in the solar arrays), as well as 90% confidence using bootstrapping (Manly 1997). Bootstrapping is a computer simulation technique that is useful for calculating point estimates, variances, and confidence intervals for complicated test statistics. A total of 1,000 bootstrap replicates was used for each variable including of searcher efficiency (p), probability of a carcass persisting to the next search ($\hat{r}$), adjusted search interval and observed fatalities. From these bootstrap samples, the probability of available and detected was calculated and applied to the bootstrapped observed fatalities. The lower 5th and upper 95th percentiles of the 1,000 bootstrap estimates provide estimates of the lower limit and upper limit of an approximate 90% confidence interval on all estimates.

2.5 Incidental Reporting

Some detections were outside standardized search areas, or were within search areas but not observed during standardized searches. Such detections were found by either WEST avian biologists or operations personnel and were considered “incidental” detections. When found by operations personnel, these detections were reported to WEST avian biologists for documentation. Data on incidental detections are reported here, as well as in the Desert Sunlight SPUT Avian Injury and Mortality Report Forms, March 2015 - February 2016. All detections made in search areas during the reporting period were included in fatality estimates, regardless of whether they were detected incidentally or during searches.

3 MONITORING RESULTS

3.1 Summary of Avian Detections

Figures 6 – 9 show the location of detections found during the monitoring year. Detailed areas of carcass locations along the gen-tie line are provided in Appendix A. During the 2015 – 2016 monitoring year, a total of 149 avian detections (including all stranded and injured birds and incidental detections) of 19 guilds and including 53 identified species were recorded (Table 4; Figure 8, 9, 10, and 11). The most numerous detection of an identified species was of American coot (*Fulica americana*) with 12 detections, followed by mourning dove (*Zenaida macroura*; n = 6). The highest detection in the solar arrays were American coot (n = 9), followed by western grebe (*Aechmophorus occidentalis*; n = 5) with no other species with more than four detections. The only species observed along the fence were American coot (n = 1), common raven (*Corvus corax*; n = 1), common loon (*Gavia immer*; n = 1), white-winged dove (*Zenaida asiatica*; n = 1), and mallard (*Anas platyrhynchos*; n = 1). Eurasian collared-dove (*Streptopelia decaocto*; n = 4) and orange-crowned warbler (*Oreothlypis celata*; n = 3) were the species with the most detections along the gen-tie/road. No bats were detected during the 2015 – 2016 monitoring year. For fresh carcasses, body weights and weather conditions the preceding nights are described in Appendix B.

The majority of detections (n = 98, or 65.8% of total detections) occurred at the solar arrays (Tables 4, 5, and 6). Forty-one detections (27.5%) occurred along the gen-tie line, seven along the fence and three at buildings. There do not appear to be major concentration areas of detections within the solar arrays (Figures 6, 7). One hundred thirteen detections (75.8%) were made during standardized carcass searches and 36 (24.2%) were documented as incidentals.

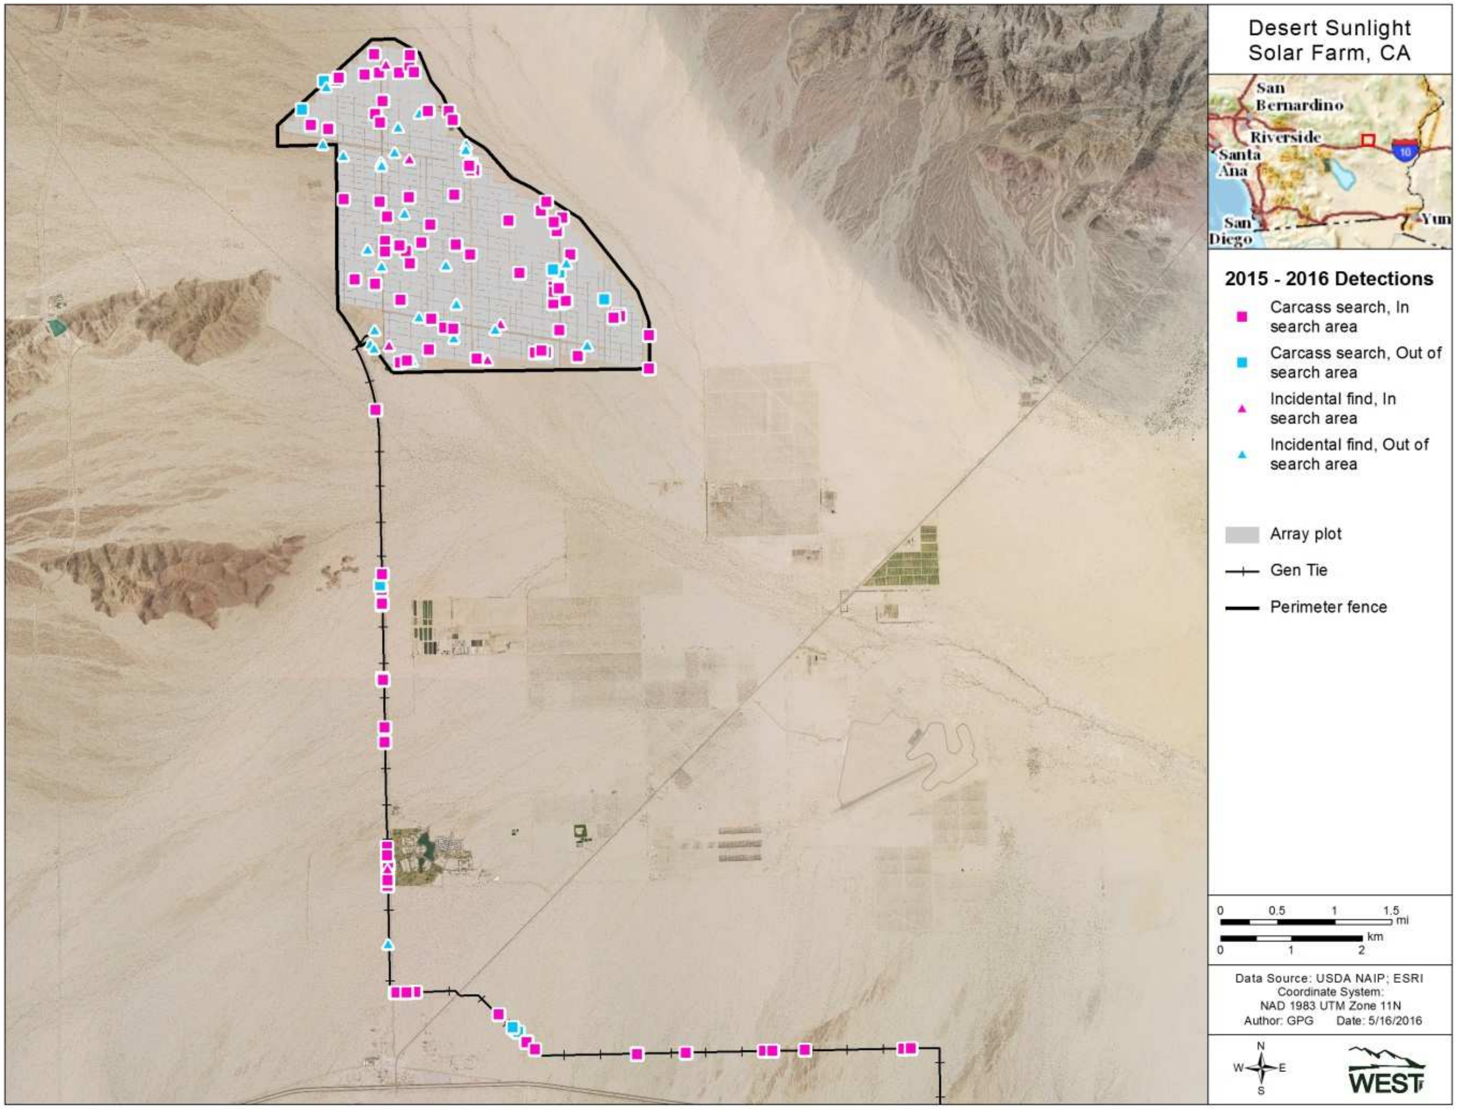

Figure 8. Areas of standardized searches and detections (those made during searches and those made incidental to operations and maintenance) at the solar field, visitor center, overhead lines within the fence, and the gen-tie line at Desert Sunlight Solar Farm Project during the 2015 – 2016 monitoring year (March 1, 2015 – February 28, 2016).

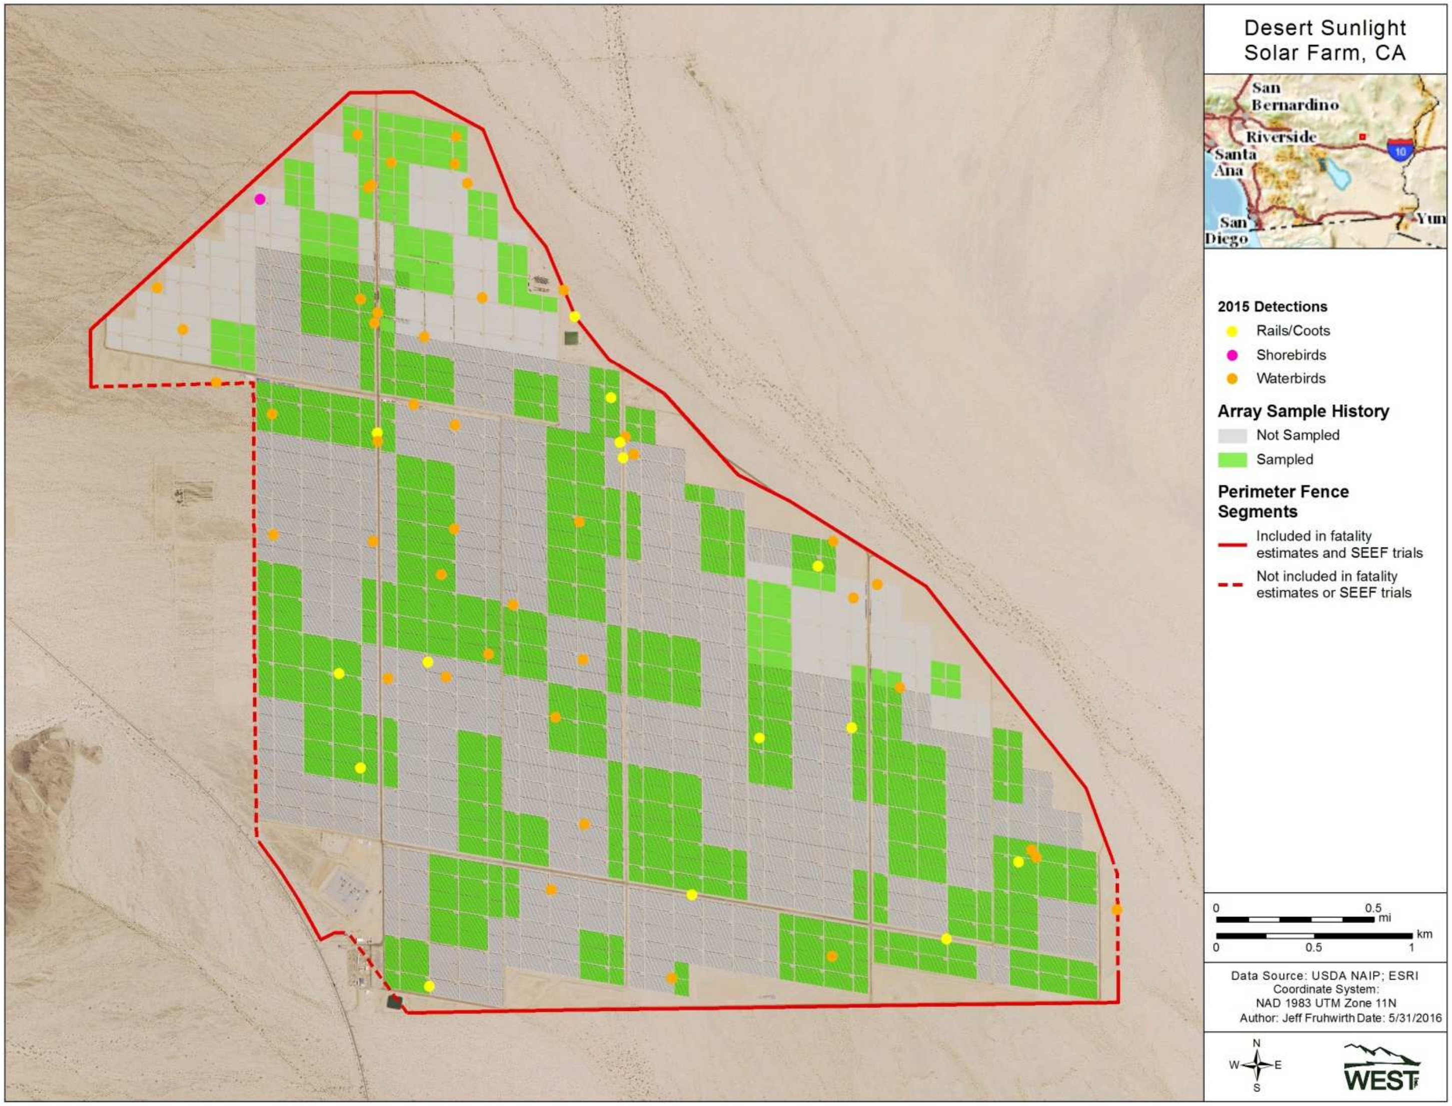

Figure 9. Location of water-associated bird carcass detections throughout the solar field, visitor center, and overhead lines within the fence at Desert Sunlight Solar Farm Project during the 2015 – 2016 monitoring year (March 1, 2015 – February 28, 2016).

[1] Ring-necked pheasants are used for bias trials and the two detections were likely from trial carcasses; however, ring-necked pheasants have been reported in Riverside County, CA south of the Project area near the Salton Sea (eBird 2015). Thus, we cannot be certain that these detections were exclusively from trial carcasses.

[2] See literature cited for migration behavior references; information for most species was taken from the respective species accounts found in The Birds of North America website (BNA 2016); where information on migration behavior was lacking in BNA accounts, Newton (2008) or Murray (2004) were used.

3.2 Suspected Cause of Avian Mortality

Most carcasses observed do not show clear signs of cause of death (Table 5 and 6). Evidence of collision as cause of death could include broken neck or beak, or bird imprint in the dust on a solar panel, but only a few carcass incidents had such evidence. There were 149 birds detected during the 2015 – 2016 monitoring year. Most of the detections were assigned an unknown cause of death; however 19.5% were suspected to be due to collision (with gen-tie, fence and solar arrays), 5.4% stranded, and 1.3% were due to predation (Table 5). There were 66 water-associated birds detected during the 2015 – 2016 monitoring year. Most were assigned unknown cause of death; however 10.6% were stranded, and 9.1% were likely collision-caused (Table 6).

Table 5. Total bird detections (including incidentals) by Project component and suspected cause of death during the 2015 – 2016 monitoring year (March 1, 2015 – February 28, 2016) at the Desert Sunlight Solar Farm Project, Riverside County, California.

	Suspected Cause of Death*				
Project Component	**Collision**	**Predation**	**Stranded**	**Unknown**	**Percent of Total Avian Fatalities**
Fence	1	0	0	6	4.7
Building	0	0	0	3	2.0

* Suspected cause of death was assigned based on evidence available on the detection, evidence available on Project infrastructure, and proximity of detection to Project infrastructure. Detections that had evidence of scavenging and lacked evidence on Project infrastructure were assigned as “unknown” because it cannot be determined whether the event was caused by predation or interaction with Project infrastructure. Detections that were intact (i.e., no evidence of scavenging) and located in close proximity to Project infrastructure (e.g., found directly beneath overhead lines) had a suspected cause of death attributed to the respective Project component. However, there is substantial uncertainty associated with cause of death assignments because no events were directly observed.

Table 6. Total waterbird detections (including incidentals) by Project component and suspected cause of death during the 2015 – 2016 monitoring year (March 1, 2015 – February 28, 2016) at the Desert Sunlight Solar Farm Project, Riverside County, California.

Percent of Total	**9.1**	**0**	**10.6**	**80.3**	**100.0**

* Suspected cause of death was assigned based on evidence available on the detection, evidence available on Project infrastructure, and proximity of detection to Project infrastructure. Detections that had evidence of scavenging and lacked evidence on Project infrastructure were assigned as “unknown” because it cannot be determined whether the event was caused by predation or interaction with Project infrastructure. Detections that were intact (i.e., no evidence of scavenging) and located in close proximity to Project infrastructure (e.g., found directly beneath overhead lines) had a suspected cause of death attributed to the respective Project component. However, there is substantial uncertainty associated with cause of death assignments because no events were directly observed.

3.3 Temporal Patterns of Avian Detections

Both spring and fall migration seasons were seven-day searches, while summer and winter had a 21-day average search interval, so interpretations of temporal patterns should keep those differences in mind. The number of detections recorded per day represents those discovered during standardized carcass searches as well as those discovered incidentally. For each day in which there were six or more detections made, an Avian Injury & Mortality Report form (in accordance with Special Utilities Permit Condition H.1(c)) was submitted within 24 hours to the USFWS, BLM, and CDFW. The 2015 – 2016 monitoring year was characterized by a peak in avian detections during the fall season. The number of avian detections recorded daily during the 2015 – 2016 monitoring year ranged from zero to six (Figure 12). On September 22, 2015, six detections were reported. During all other survey days, five or fewer birds were detected.

The highest peaks in avian detections at the arrays and along the gen-tie occurred during the fall season, while there was no apparent pattern observed along the fence or at buildings as only a few were detected at these locations (Figure 13). The greatest number of avian detections occurred during the month of October (Figure 13; n = 44) followed by September (n = 38), with waterbird and waterfowl detections greatest during the same two months (Figure 13).

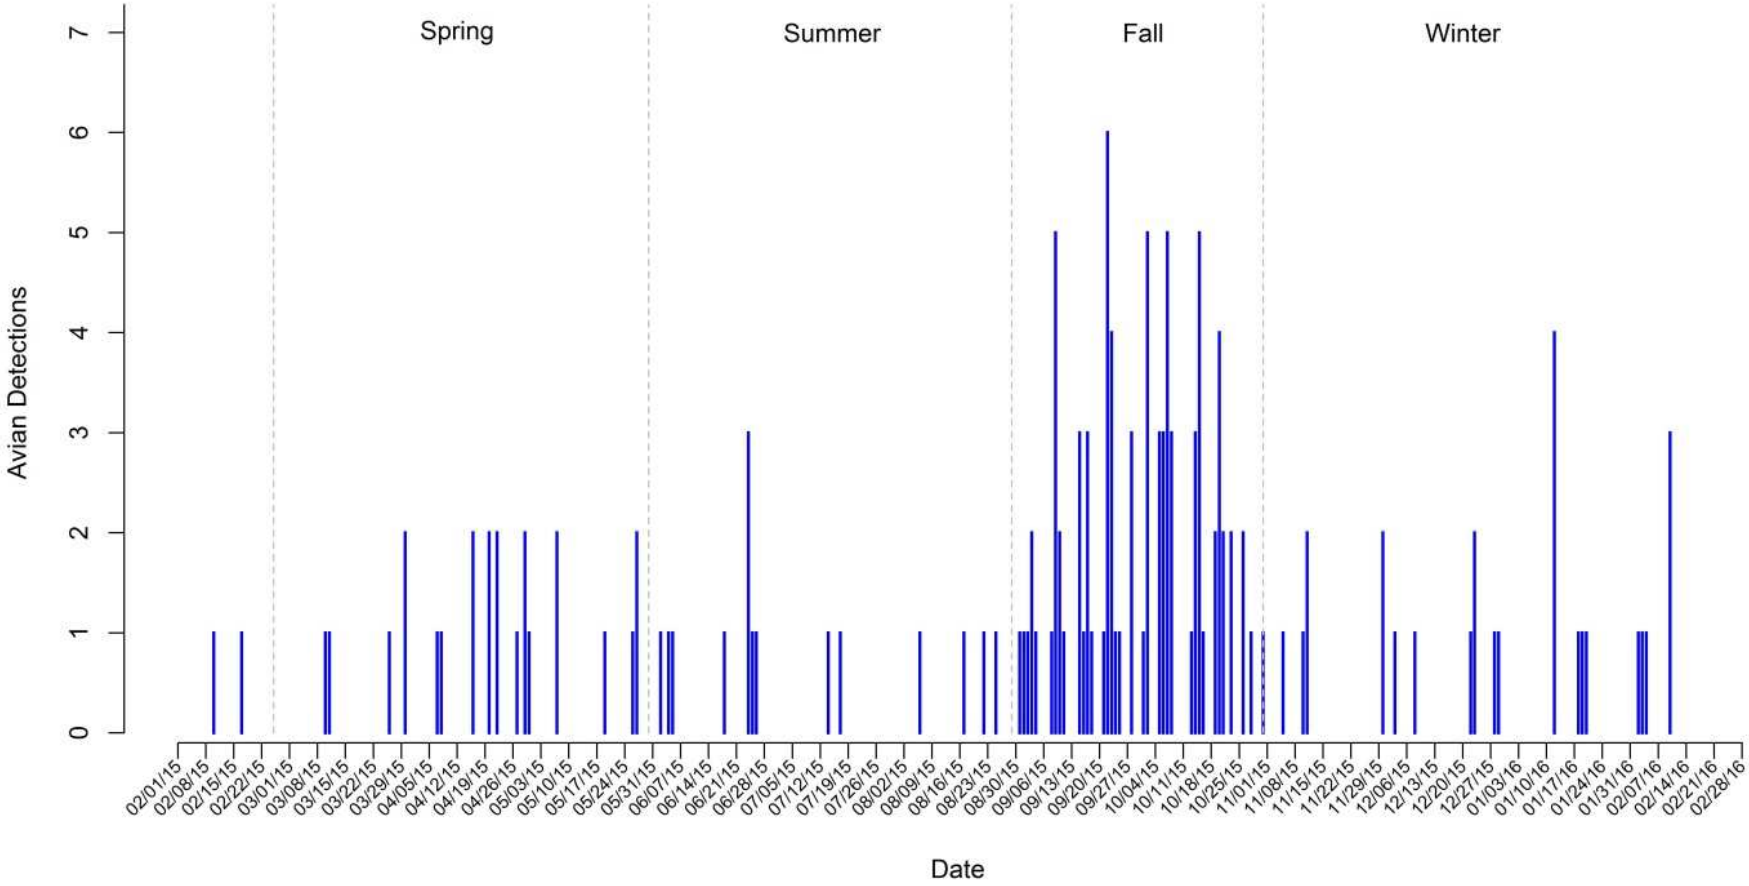

Figure 12. Total count of detections (including incidentals) by date during the 2015 – 2016 monitoring year (March 1, 2015 – February 28, 2016) at the Desert Sunlight Solar Farm Project, Riverside County, California.

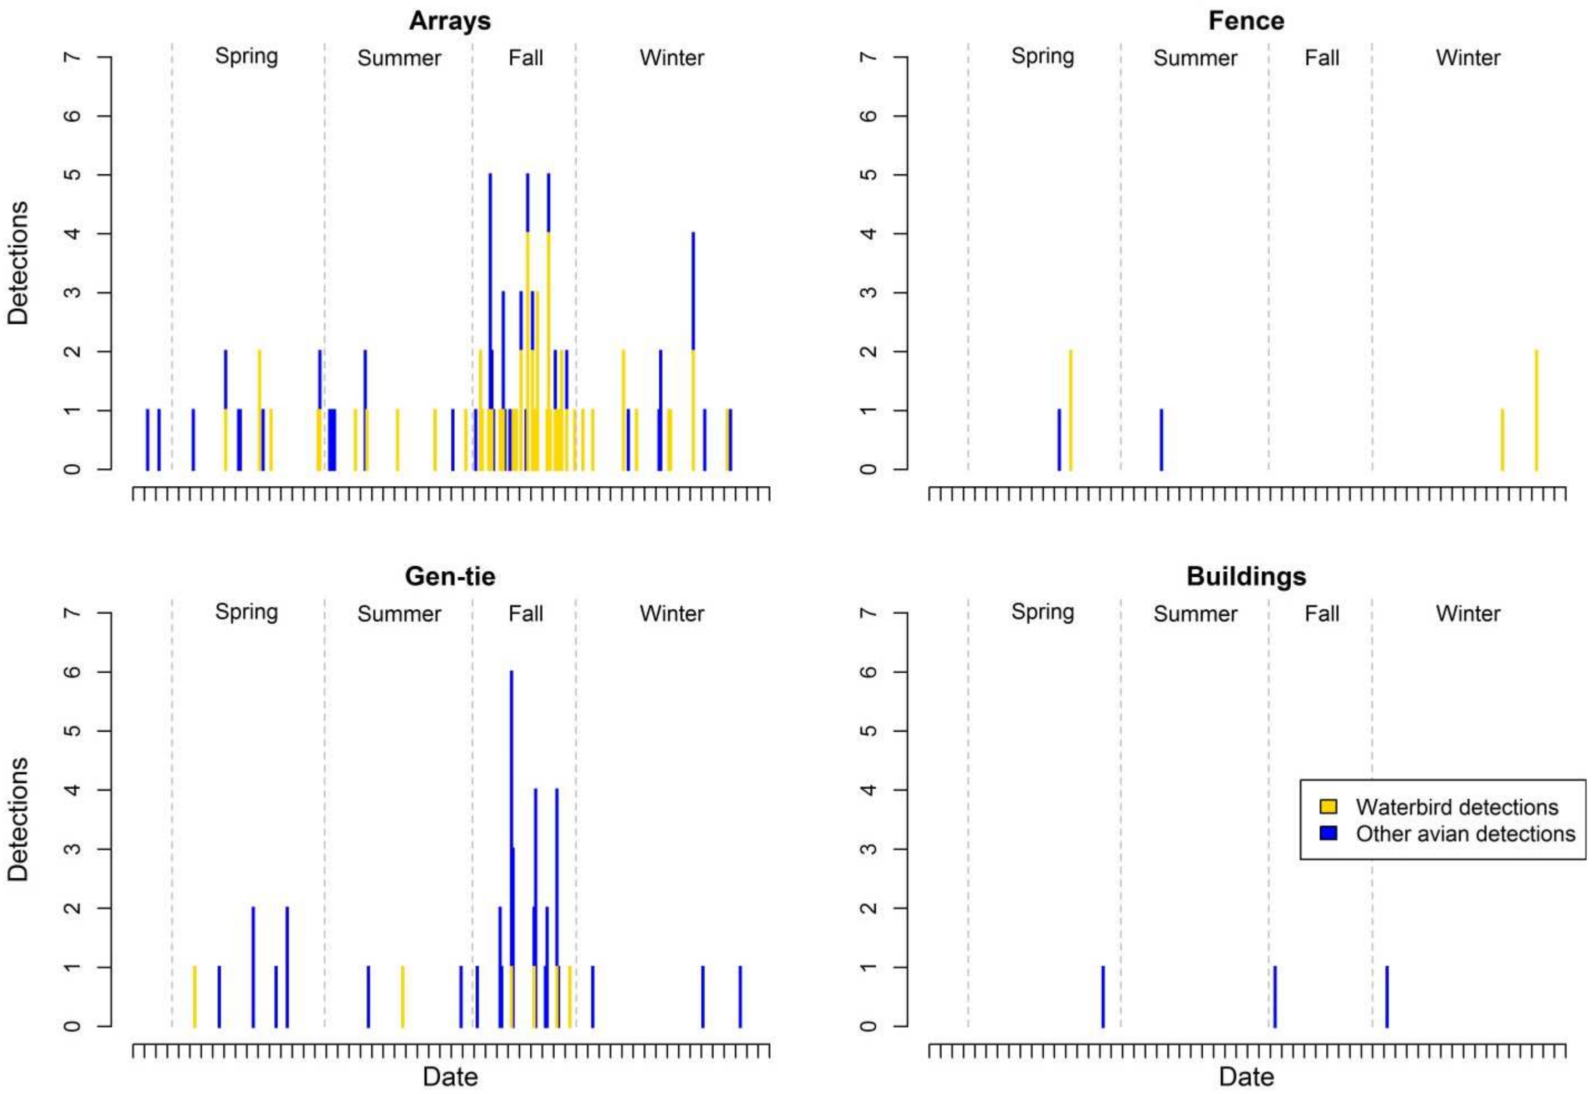

Figure 13. Total count of detections (including incidentals) by date for both waterbirds/waterfowl detections and all avian detections during the 2015 – 2016 monitoring year (March 1, 2015 – February 28, 2016) at the Desert Sunlight Solar Farm Project, Riverside County, California.

3.4 Spatial Distribution of Avian Detections

3.4.1 Detections by Project Component

During the 2015 – 2016 monitoring year, detections were documented from the solar arrays, the Visitor Center, the fence, and the gen-tie line (Tables 4 and 5). There were 98 detections (65.8% of all detections) at the solar arrays. Forty-one detections (27.5% of annual total) were along the gen-tie line, seven were along the fence (4.7% of annual total) and three detections (2.0% of annual total) were at the Visitor Center. The majority of non-water-associated birds (n = 43; Table 7) and water associated birds (n = 55; Table 8) were detected at the solar arrays, and is not unexpected given the large spatial extent of the arrays (over 4000 acres).

Table 7. Total non-waterbird detections by Project component and detection category during the 2015 – 2016 monitoring year (March 1, 2015 – February 28, 2016) at the Desert Sunlight Solar Farm Project, Riverside County, California. Only carcasses found within search areas were included in fatality estimates.

Project Component	Inside carcass search area		Outside carcass search area	
	Carcass search	Incidental	Carcass search	Incidental
Fence	1	0	1	0
Buildings	0	0	0	3
Gen-tie line	28	1	5	1
Solar arrays	31	2	2	8
Total	**60**	**3**	**8**	**12**

Table 8. Total waterbird detections by Project component and detection category during the 2015 – 2016 monitoring year (March 1, 2015 – February 28, 2016) at the Desert Sunlight Solar Farm Project, Riverside County, California. Only carcasses found within search areas were included in fatality estimates.

Project Component	Inside carcass search area		Outside carcass search area	
	Carcass search	Incidental	Carcass search	Incidental
Fence	3	0	1	1
Buildings	0	0	0	0
Gen-tie line	5	0	0	1
Solar arrays	34	6	2	13
Total	**42**	**6**	**3**	**15**

3.4.2 Detections at solar collector assemblies

Upon ocular examination, fatalities among the solar arrays appear evenly dispersed throughout the Project site (Figure 14). The distance between the average location of the search areas and the average location of fatalities found inside search areas is 73 meters suggesting no obvious concentration of fatalities in a particular direction (e.g. more fatalities towards the west or towards the south side of the facility).

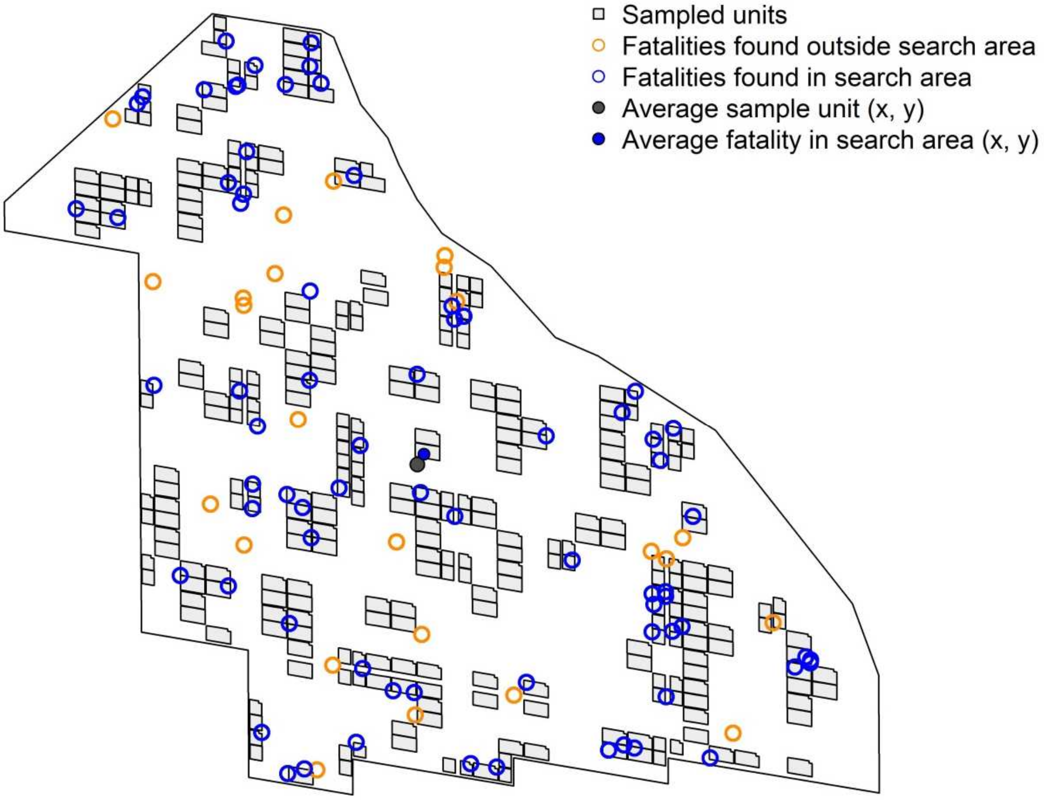

Figure 14. Spatial distribution of carcass search and incidental detections from SCAs during the 2015 – 2016 monitoring year (March 1, 2015 – February 28, 2016) at the Desert Sunlight Solar Farm Project, Riverside County, California.

3.4.3 Feather Spot Detections

Thirty-eight (25.5%) of the 149 detections made during the 2015 – 2016 monitoring year consisted only of feather spots. Along the gen-tie, 14 of 41 detections (34.1%) were feather spots. Twenty-two of 98 detections (22.5%) in the solar arrays were feather spots. Along the fence, two of seven total detections (28.6%) were feather spots.

3.5 Detections of Injured or Stranded Birds

There were six detections of stranded or injured birds during the 2015 – 2016 monitoring year, each of which occurred during the fall monitoring period. Three injured birds were detected within the solar arrays (ruddy duck [*Oxyura jamaicensis*], western grebe [*Aechmophorus occidentalis*], and mourning dove [*Zenaida macroura*]). Three stranded but uninjured birds were detected in the arrays (common loon [*Gavia immer*]) and ruddy duck and eared grebe [*Podiceps nigricollis*]). The injured mourning dove and ruddy duck were transported to wildlife rehabilitation facilities; the ruddy duck was released by the rehabilitator on the same day. The injured western grebe died before it got to a rehabilitation facility. The stranded ruddy duck, eared grebe, and common loon were evaluated for a short period for injuries and general stress and when none were observed, released at Lake Tamarisk.

3.6 Summary of Bat Detections

No bats were detected during the 2015 – 2016 monitoring year.

3.7 Carcass Persistence Trials

Data from carcass persistence trials were available from all four seasonal monitoring periods within the solar arrays and along the gen-tie line. A total of 275 carcasses were available for fitting the model.

Using carcass persistence data from the 2015 – 2016 monitoring year, survival models were fitted separately for each size class for relative quality using the corrected AICc score, as suggested in Huso (2010). The model with the lowest AICc is typically chosen as the “best” model relative to other models tested; however, any model within two AICc points of the best model is considered competitive with the best model (Burnham and Anderson 2004).

Models were fit to each size class separately to allow for the selection of different model distributions and covariate combinations to achieve the best fit for each size class. Model comparisons using AICc suggested that season and Project component location (whether at the solar field or at the overhead lines) are important predictors of carcass persistence for small, medium and large birds.

Both Project component location and season were important in the large bird persistence model. For large birds, the AICc suggested that a seasonal covariate with two categories, spring and fall data pooled and winter and summer data pooled together was not the top rated model, but within two AICc points from the top model. This model was chosen because it has similar predictive ability as the top model but also has fewer parameters to estimate. For medium birds, the best predictive model included the main effects of Project component location and season. The AICc suggested that a seasonal covariate with two categories, spring and summer data pooled and fall and winter data pooled together was the best predictive model for medium birds. The best model for small birds included the main effects of Project component location, season (with no pooling), and an interaction between Project component location and season. The best models for small, medium, and large birds followed a lognormal, Weibull, and loglogistic distribution respectively (Table 9).

Table 9. Top five carcass persistence models for each size class from the AICc model selection process. (bold) indicates chosen model. Sp = spring, Su = summer, Fa = fall, Wi = winter, and Δ = change. The covariate 'season' has no seasonal grouping.

Size	Model Predictors	Distribution	AICc	ΔAICc
Small Birds	**Project (Proj.) Location + season + Proj. Location * season**	**Lognormal**	**596.66**	**0**
	Proj. Location + season + Proj. Location * season	Exponential	597.04	0.38
	Proj. Location + season + Proj. Location * season	Loglogistic	597.07	0.41
	Proj. Location + season + Proj. Location * season	Weibull	598.76	2.10
	Proj. Location + season	Lognormal	600.00	3.34
Medium Birds	**Proj. Location + Sp/Su & Fa/Wi**	**Weibull**	**466.35**	**0**
	Proj. Location + Sp/Su & Fa/Wi	Loglogistic	467.59	1.24
	Proj. Location + Sp/Su & Fa/Wi	Lognormal	467.74	1.39
	Proj. Location + Sp/Su & Fa/Wi + Proj. Location * Sp/Su & Fa/Wi	Weibull	468.54	2.19
	Proj. Location season + Proj. Location * season	Weibull	469.65	3.30
Large Birds	**Proj. Location + season + Proj. Location * season**	**Loglogistic**	**258.71**	**0**
	Proj. Location + season + Proj. Location * season	Lognormal	259.29	0.58
	Proj. Location + Sp/Fa & Su/Wi	Loglogistic	259.34	0.63
	Proj. Location + Sp/Fa & Su/Wi	Lognormal	260.40	1.69
	Proj. Location + Sp & Su/Fa/Wi	Loglogistic	260.91	2.20

The sample size for the intercept of each of the three models was 135, 90 and 50 for small, medium, and large trial carcasses respectively.

The average probability that a carcass at the solar field or a carcass along the gen-tie persists for an average search interval (approximately 7 days for spring and fall; 21 days for summer and winter), is provided for each season and size class in Table 10. Mean (median) removal time within the solar field was 4.9 (6.0) days during spring, 12.7 (12.6) during summer, 2.5 (1.5) during fall, and 6.5 (6.0) during winter for small carcasses; 36.0 (27.8) days during spring, 36.0 (24.3) during summer, 12.2 (18.0) during fall, and 12.2 (6.8) during winter for medium carcasses; and 58.3 (31.0) days during spring, 13.7 (30.0) during summer, 58.3 (30.0) during fall, and 13.7 (5.1) during winter (Table 11). At the overhead lines, removal time was 0.8 (0.5), 0.8 (0.5), 0.4 (0.5), and 2.3 (2.5) for small birds during spring, summer, fall, and winter respectively. For medium birds, mean (median) removal time at the overhead lines was 14.4 (2.0), 14.4 (15.8), 4.9 (1.5), and 4.9 (2.5) days during spring, summer, fall, and winter respectively. Mean (median) removal time for large birds was 5.8 (19.0), 1.4 (0.5), 5.8 (3.5), and 1.4 (3.5) days during spring, summer, fall, and winter respectively (Table 11). Figure 15 shows the proportion of trial carcasses remaining as a function of days since placement and carcass model covariate (component location and/or season).

Table 10. Average probability of carcass persistence to the next search (search interval approximately 7 days during spring and fall migration periods, and 21 days during summer and winter non-migration periods)

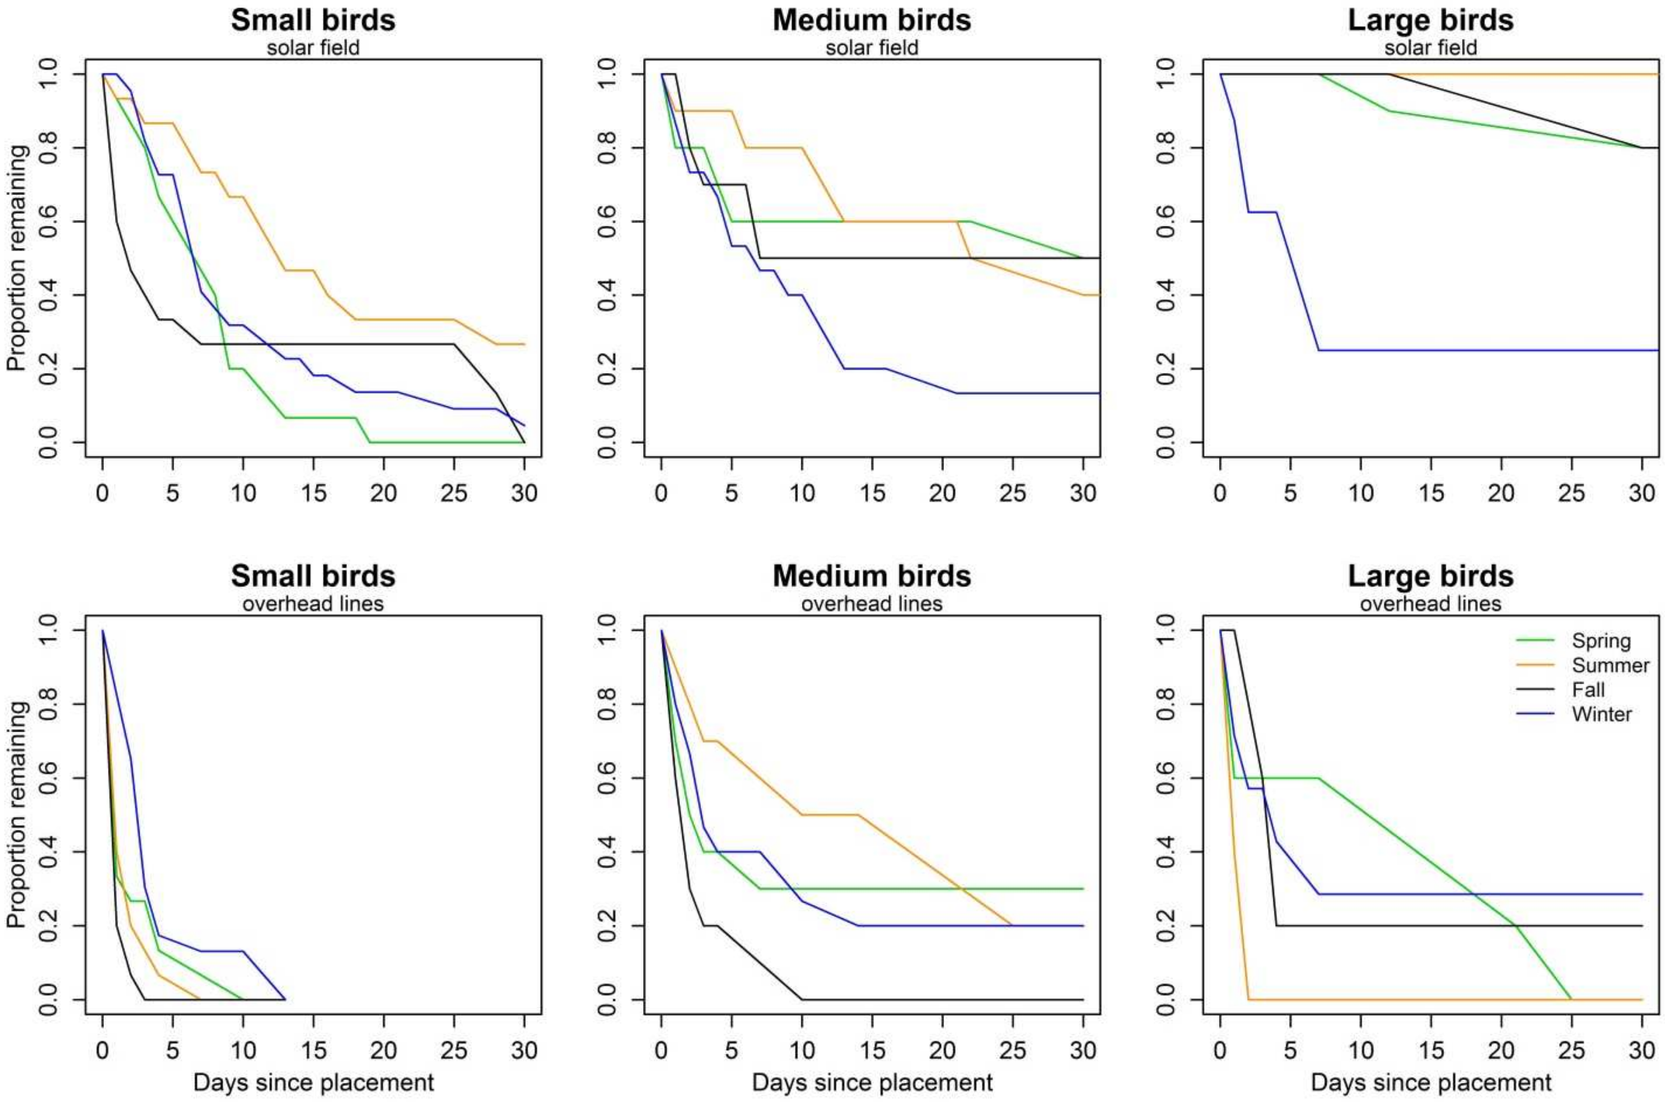

Figure 15. Proportion of trial carcasses remaining as a function of days since placement and carcass size class during the 2015 – 2016 monitoring year (March 1, 2015 – February 28, 2016) at the Desert Sunlight Solar Farm Project, Riverside County, California. Sample size used to produce each panel of the above figure was n = 67, 45, and 28 for small, medium, and large birds at the solar field and 68, 45, and 22 small, medium, and large birds at the overhead lines.

3.8 Searcher Efficiency Trials

During the reporting period, a total of 810 searcher efficiency trials were placed at the Project. Most trials were available to be found, but some disappeared before or during the trial. Overall, 360 trials were placed in the solar arrays and 336 were available to be found; 150 trials were placed along the perimeter fence (inner perimeter only) and 148 were available to be found; and 300 trials were placed along the gen-tie line and 270 were available to be found. Three observers conducted searches at the Project during fall. Searcher efficiency trials were conducted on each observer in approximate proportion to the number of searches they conducted at the Project, as follows: Sarah N. (number of trials available to be found: 281), Jennifer J. (223), Wanda B. (77), Darin B. (71), David G. (58), Pamela B. (27), Anika M. (nine), and Frank M. (eight). All trials were included in estimation of searcher efficiency. These numbers were generally in proportion to the amount of searching conducted by these biologists.

For the solar arrays, searcher efficiency was modeled separately for small, medium, and large birds. The best model for each carcass size is presented in Table 12 below. Within the solar arrays, searcher efficiency for small birds was influenced by cobble cover and season: small birds in high cobble cover in the fall had a searcher efficiency of 33.2% (CI: 13.3 – 63.9%; n = 15) and small birds in low cobble cover in the fall had a searcher efficiency of 57.8% (CI: 39.0 – 77.7%; n = 27; Table 13). Searcher efficiency for small birds in high cobble cover during winter, spring and summer was 36.0% (CI: 21.1 – 45.4%; n = 50), and small birds in low cobble cover during winter, spring and summer had a searcher efficiency of 64.5% (CI: 44.5 – 63.4%; n = 70). For medium birds, searcher efficiency within the solar arrays was similar across cobble cover classes but differed by season: in winter, medium bird searcher efficiency was 94.0% (CI 87.5 – 98.5%; n = 45), and in spring, summer and fall, medium bird searcher efficiency was 83.2% (CI: 76.5 – 89.8%; n = 63). For large birds, searcher efficiency among the solar arrays differed between migration seasons (spring and fall) and non -migration seasons (summer and winter). Searcher efficiency during spring and fall for large birds was 83.9% (CI: 72.0 – 94.3%; n = 31). Searcher efficiency for large birds during summer and winter was 100% with no variance (n = 35). Sample sizes refer to numbers of trial carcasses that were available to be found, not numbers of trial carcasses that were placed (Figure 5 - 7).

For the fence, the model that included an effect of carcass size, and season (with data from spring and winter pooled and summer and fall pooled) was chosen as the most supported model to estimate searcher efficiency (Table 14). Along the fence, searcher efficiency was 65% (CI: 52 – 77%), 94% (CI: 88 - 100%), and 100%, for small, medium, and large carcasses, respectively during spring and winter and 87% (CI: 77 – 97%), 98% (CI: 96 – 100%), and 100% for small, medium, and large carcasses respectively during summer and fall (Table 13).

For the gen-tie line, the chosen model included main effects of size, season (with data from spring and summer data pooled and fall and winter pooled), and visibility class, with an interaction between visibility class and season (Table 14). It ranked second by AICc but was only 0.59 AICc points from the top model. It was chosen because it has similar predictive performance as the top model, but with fewer parameters to estimate. For the easy visibility class, searcher efficiency was 67% (CI: 53 – 81%), 89% (CI: 80 – 95%), and 89% (CI: 80 – 96%) for small, medium, and large carcasses, respectively during spring and summer and 57% (CI:46 – 68%), 84% (CI: 75 – 91%), and 85% (CI: 73 – 93%) for small, medium, and large birds respectively during fall and winter (Table 13). For the difficult visibility class, searcher efficiency was 75% (CI: 62 – 86%), 92% (CI: 86 – 97%), and 92% (CI: 84 – 97%) for small, medium, and large birds respectively during spring and summer and 33% (CI: 22 – 44%), 65% (CI: 53 – 77%), and 67% (CI: 51 – 82 %) for small, medium, and large birds respectively during fall and winter (Table 13). A summary of searcher efficiency estimates are reported in Appendix C.

3.9 Fatality Estimates

Fatality estimates were calculated separately for each component (solar arrays, fence, and overhead lines). There were 149 detections during the 2015 – 2016 monitoring year. Fatalities found in the sample standardized search areas that were estimated not less than twice the length of the search interval were included. This conservative definition was used due to uncertainty in aging carcasses and should result in a positive (overestimate) bias. Detections used in the analysis, bias corrections, fatality estimates, and 90% confidence intervals are detailed in Appendix C.

Using the Huso (2010) fatality estimator, during the 2015 – 2016 monitoring year, there were an estimated total of 1,328 bird carcasses (CI: 1,007 – 2,303) at the Project (all components combined). There were an estimated 53 (CI: 28 – 85) large birds, 336 (CI: 246 – 449) medium birds, 881 (CI: 566 – 1,843) small birds, and 58 (CI: 22 – 143) birds of unknown size at the Project (all components combined; Table 15).

The model estimates 628 (CI: 496 – 951) bird carcasses (152/1000 acres, 1.16/nameplateMW) at the solar arrays, 688 (CI: 364 – 1,567) along the gen-tie line and 11 (CI: 2 – 26) at the fence. Estimates of fatalities along the gen-tie are heavily influenced by the high rates of scavenging observed during the limited trials at the gen-tie (i.e., large correction factors) and are likely very unreliable. Adjusted fatality estimates for each Project component are provided by guild in Table 16. A complete list of estimates by Project component and carcass size class with confidence intervals is presented in Appendix C.

Table 15. Adjusted fatality estimates by size and guild during the 2015 – 2016 monitoring year (March 1, 2015 – February 28, 2016) at the Desert Sunlight Solar Farm Project, Riverside County, California

4 DISCUSSION

The 2015 – 2016 monitoring year represented the first full year of standardized monitoring at Desert Sunlight. Searcher efficiency and carcass persistence trials were conducted concurrently at the solar arrays, fence lines, and along the gen-tie line. Data from these trials were used to produce fatality estimates adjusted for searcher efficiency and carcass persistence bias. The results provided in each seasonal report were considered preliminary because estimating carcass persistence, searcher efficiency, and adjusted numbers of fatalities within each season represents information based on a limited sample size. For this annual report, the analysis is comprehensive, with data from all four seasons included in the analysis.

4.1 Carcass Persistence and Searcher Efficiency Trials

The degree to which carcasses persist on the landscape depends on a variety of factors reflecting seasonal and inter-annual variation in habitat, climate, and the scavenger community. The composition and activity patterns of the scavenger community often vary seasonally as birds migrate, new juvenile birds and mammals join the local population, and mammalian scavengers variably hibernate or estivate. The scavenger community may also vary substantially from year to year because of variation in annual reproduction and survival related to changes in landscape condition. Climatic conditions that vary seasonally and annually also may contribute to variation in carcass decay and removal rates due to variation in temperatures, solar insolation, wind patterns, the frequency of flooding events, and other factors. Carcass persistence was low along the gen-tie line, while persistence rates were longer within the Project fence. Overall, carcass persistence rates were longer for medium and large birds compared to smaller birds but there was variation by season and Project component. The longer persistence rates for larger sized birds is a consistent result seen in many other studies (Smallwood et al. 2010, and Morrison 2002).

The experimental bias trials themselves may influence scavenging on site. The large number of carcasses used in trials may be attracting scavengers to the Project site and negatively influencing the bias adjustments for the fatality estimates. Scavengers may learn from visual and olfactory cues that carcasses are being placed for trials. Placing carcasses in the early morning, placing fake cameras at locations without carcasses, and varying the clothes of the biologists placing the carcasses are all methods that were used to try to reduce this bias.

Searcher efficiency was influenced by carcass size, season, and cobble cover within the solar arrays. Some of the relationships that were apparent were not always explainable and expected from a biological perspective (e.g. some of the seasonal effects), but were still included in the final models. Consideration for simplifying the models will be given for the 2nd year monitoring data analysis and reporting.

4.2 Fatalities Timing and Guild/Species Composition, and Other Fatality Characteristics

There were no large mortality events (e.g., >30 birds found on a day) during this 2015 – 2016 monitoring period. More detections occurred during the fall season, beginning in early September and continuing through late October. This peak in detections coincides with the fall bird migration period as well as the time when population sizes are typically highest during fledging in the summer. The increased detections in the fall were primarily due to detections of water-associated birds, especially during the month of October. The peak observed during the fall was apparent within both the solar arrays and along the gen-tie. At the solar arrays, the increase in the fall was mostly waterbird species, whereas the fall increase observed along the gen-tie was primarily non-water associated species.

During the 2015 – 2016 monitoring year, the 149 avian detections (including all stranded and injured birds and incidental detections) consisted of 19 guilds and included 53 identified species. The most numerous detection of an identified species was American coot with 12 detections, most of which were at the solar arrays. Mourning dove (n = 6) was the next most commonly detected species. The most numerous detection in the solar arrays was American coot (n = 9), followed by western grebe, with no other species with more than four detections. The only species observed along the fence were American coot (n = 1), common raven (n = 1), common loon (n = 1), white-winged dove (n = 1), and mallard (n = 1). Eurasian collared-dove (n = 4) and orange-crowned warbler (n = 3) were the species with the most detections along the gen-tie/road.

There were no strong spatial patterns observed within the solar arrays or along the fenceline. Along the gen-tie line, there were a few clusters of detections, the majority of which were small bird species.

4.3 Causation

Detections attributed to an unknown cause accounted for approximately 74% of all detections during the 2015 – 2016 monitoring year. Determining a cause of mortality from a feather spot or scavenged bird is challenging because there is rarely visible evidence available on which to determine a cause of death. Especially for passerine species found on the Project, an unknown but potentially measurable number of the carcasses might have been caused by factors other than collision with the Project facilities. Due to this uncertainty of causation, some studies have estimated background fatality estimates at reference or control areas. There have been two studies of background mortality at solar facilities: CVSR and Topaz had conducted background avian fatality monitoring in an effort to assess causation (H.T Harvey and Associates 2014; Althouse and Mead Inc. 2014). These studies were designed to try and quantify the potential degree to which fatalities were likely the result of interactions with facility infrastructure (PV panels, etc.) or whether some of the fatalities might be unrelated to the presence of the facility. Mortality at these two Project sites was not unlike the estimates of background mortality observed on nearby reference sites. Given the low density of carcasses found within the solar arrays (<0.2/acre/year), a large field effort would likely be required to characterize background mortality with reasonable levels of precision if background rates were similar to the rates in the arrays.

In addition to issues associated with background mortality, multiple feather spots found on site may be from the same detection. Game cameras trained on carcasses for carcass persistence trials at the Project have documented the potential for multiple feather spots originating from a single trial carcass. Ravens and turkey vultures, and possibly roadrunners, dislodge feathers from their attachment to the skin of the carcass during the scavenging process. There are a very large number of potential feather spots present from a single bird carcass. This large number occurs because a feather spot is defined as at least two or more primary flight feathers, at least five or more tail feathers, or two primaries within five m (16.4 ft) or less of each other, or a total of 10 or more feathers of any type concentrated together in an area of three square m. Thus, the presence of feather spots among the detections for the Project would inflate the fatality estimate based on the potential for multiple feather spots, resulting from one fatality being counted as separate detections if feathers are either blown around the site, scattered by predators (e.g., plucking by ravens), resulting from predation not associated with the facility, or resulting from other unrelated causes. Nonetheless, feather spots are included in the analysis here to provide a more conservative estimate of fatality. If feather spots were excluded from the analysis, the overall estimates would be reduced by approximately 25%.

4.4 Fatality Estimates

The estimated density of carcasses for the Project components within the fence (solar arrays and fence) is only 0.15 carcasses/acre/year. More carcasses were estimated for the gen-tie than the solar arrays; however, the estimates for the gen-tie are unreliable due to very high carcass removal rates along that Project component. Approximately 270 water-associated carcasses (or 0.06 per acre) were estimated for the solar arrays.

1.0 INTRODUCTION

Desert Sunlight 250, LLC and Desert Sunlight 300, LLC (collectively, Desert Sunlight), has constructed and will operate the Desert Sunlight Solar Farm Project (Project), which consists of two main components: 1) a 550-megawatt (MW) photovoltaic (PV) generating facility; and 2) a 220-kilovolt (kV) generation interconnection (Gen-tie) line. The Project comprises approximately 1,700 hectares (ha; 4,200 acres) of land administered by the Bureau of Land Management (BLM) six miles north of Desert Center in Riverside County, California (Figure 1).

Information on pre-construction site conditions, avian and bat species present at the Project, risk assessment, and conservation measures implemented during pre-construction and construction phases are found in the Project's "Avian and Bat Protection Plan, Desert Sunlight Solar Farm Project, BLM Case File Number CACA-48649, Riverside County, California" (Ironwood Consulting 2011). The Avian and Bat Protection Plan (ABPP) was included as part of Appendix H in the Desert Sunlight Solar Farm Project, California Desert Conservation Area Plan Amendment and Final Environmental Impact Statement (USDI BLM 2011) and the Project received a Record of Decision from the Secretary of the Department of the Interior on August 09, 2011. Avian and Bat Protection Plans have since been renamed, and are presently known as Bird and Bat Conservation Strategies (BBCS). This BBCS replaces the ABPP and was developed in coordination with BLM to provide a written record of the Project's post-construction efforts to monitor potential project impacts to birds and bats and to document conservation measures that have been or will be taken to avoid, minimize, and/or mitigate for potential impacts. After introductory material on project description, the BBCS purpose, and regulatory framework, this BBCS addresses post-construction monitoring and adaptive management.

Figure 1. Location of the Desert Sunlight Solar Farm Project, Riverside County, California.

1.1 Purpose

The primary purpose of this BBCS is to describe post-construction monitoring protocols that will identify the extent of mortality and injury to bird and bat species and guide the adaptive management process intended to avoid, minimize, and/or mitigate impacts consistent with the Project's approval documentation. This BBCS includes the following objectives:

- Identify operational activities that may increase potential adverse effects to avian and bat species on and adjacent to Project components;
- Describe measures that were taken before and during construction to minimize and document mortality;
- Provide details for an avian fatality monitoring plan to be conducted post-construction, including applicable approved protocols that would be used for any surveys and/or monitoring;
- Specify the adaptive management process that will be used to address potential adverse effects on these species.

1.2 Regulatory Setting

Several federal and state laws and regulations, including National Environmental Policy Act (NEPA), the Endangered Species Act (ESA), the Migratory Bird Treaty Act (MBTA), the Bald and Golden Eagle Protection Act (BGEPA), and California Endangered Species Act, provide the foundation for the development of this BBCS.

1.2.1 National Environmental Policy Act

Under NEPA (42 United States Code [USC] §§ 4321-4370h), federal agencies are required to prepare an environmental impact statement (EIS) for any major federal action significantly affecting the quality of the human environment. An EIS must include an examination of the environmental impacts of a proposed project, a reasonable range of alternatives for a project, and other related matters. The environmental impacts of the Project have been addressed in the Final EIS and ROD (BLM 2011a,b). This BBCS implements Mitigation Measure (MM) WIL-5 in the Project's ROD.

1.2.2 Endangered Species Act

Certain species at risk of extinction, including many birds and bats, are protected under the federal ESA. The ESA defines and lists species as "endangered" and "threatened" and provides regulatory protection for the listed species. The ESA provides a program for conservation and recovery of threatened and endangered species. Section 7(a)(2) of the ESA directs all federal agencies to insure that any action they authorize, fund, or carry-out does not jeopardize the continued existence of an endangered or threatened species or destroy or adversely modify designated or proposed critical habitat (collectively, referred to as protected resources).

1.2.3 Migratory Bird Treaty Act

The MBTA (16 USC §§ 703, *et seq.*), makes it unlawful to "pursue, hunt, take, capture or kill; attempt to take capture or kill; possess; offer to or sell, barter, purchase, or deliver; or cause to be shipped, exported, imported, transported, or received any native migratory bird, part, nest, egg, or product." The MBTA, enforced by USFWS, protects all MBTA-listed migratory birds within the United States. In the continental U.S., native non-covered species generally belong to the Order Galliformes. Common non-native species not protected by the MBTA include rock pigeon (*Columba livia*), Eurasian collared-doves (*Streptopelia decaocto*), European starling (*Sturnus vulgaris*), and house sparrow (*Passer domesticus*; USFWS 2005). Although permits may be obtained to collect MBTA-listed birds for scientific purposes or to destroy depredating migratory birds, the MBTA does not provide any permit mechanism authorizing the incidental take of migratory birds in connection with otherwise lawful activities. Nevertheless, federal agencies such as the BLM have been directed to evaluate the effects of its actions on migratory birds, with an emphasis on species of concern (per Executive Order 13186).

1.2.4 Bald and Golden Eagle Protection Act

The BGEPA (16 USC §§ 668-668d) prohibits the take, defined as "pursue, shoot, shoot at, poison, wound, kill, capture, trap, collect, molest, or disturb," of any bald eagle (*Haliaeetus leucocephalus*) or golden eagle (*Aquila chrysaetos*). Through recent regulation (50 Code of Federal Regulations [CFR] § 22.26; USFWS 2009), the USFWS can authorize take of bald and golden eagles when the take is associated with, but not the purpose of, an otherwise lawful activity and cannot practicably be avoided. The USFWS has issued Eagle Conservation Plan Guidance (USFWS 2013a) for land-based wind energy projects to help project proponents avoid unanticipated take of bald and golden eagles and comply with the BGEPA. Although the guidelines were developed for land-based wind energy projects, certain components of eagle surveys and monitoring are applicable to other renewable energy projects, including PV solar plants, and have been incorporated into this BBCS as appropriate.

1.2.5 California Department of Fish and Game Codes

<u>CDFG Code Sections 2050-2085</u> – These codes encompass the applicable declarations and definitions of the California Endangered Species Act (CESA).

<u>CDFG Code Sections 3503 and 3503.5</u> – These codes state that it is unlawful to take, possess, or needlessly destroy the nest or eggs of any bird (including birds of prey) or take, possess, or destroy birds of prey, except as otherwise provided by this code or any regulation made pursuant thereto.

<u>CDFG Code Sections 3511, 4700, 5050, and 5515</u> – These state laws classify and prohibit the take of "fully protected" bird, mammal, amphibian/reptile, and fish species in California.

<u>CDFG Code Section 3513</u> – This code prohibits any take or possession of birds that are designated by the MBTA as migratory non-game birds except as allowed by federal rules and regulations promulgated pursuant to the MBTA.

CDFG Code Section 4150 – This code defines all mammals that naturally occur in California as non-game mammals with exceptions for those defined as game mammals, fully protected mammals, or fur-bearing mammals. Non-game mammals or parts thereof may not be taken or possessed except as otherwise provided by this code or any regulation made pursuant thereto.

1.3 Corporate Policy and Coordination

Desert Sunlight maintains a commitment to work cooperatively to minimize adverse impacts to protected bird and bat species. Through the planning and construction stages of the Project, Desert Sunlight and its contractors and consultants worked in coordination with federal and state agency personnel regarding necessary wildlife surveys, siting considerations, mitigation measures and adaptive management to ensure that potential issues that could affect bird and bat species were identified as early as possible in the planning process and addressed through appropriate design, mitigation and adaptive management measures. Desert Sunlight will continue to work with the agencies to implement conservation measures intended to avoid, minimize, and/or mitigate potential impacts to bird and bat species, including those measures identified in this BBCS.

2.0 PROJECT DESCRIPTION

The Project is a PV solar power plant being developed on approximately 1,700 ha (4,200 acres) of public land administered by the BLM in Riverside County, California, approximately 9.7 km (six miles) north of the rural community of Desert Center (Figure 1). Project construction is anticipated to be concluded on or about January 2015. The Project consists of two main components: 1) a 550 MW PV generating facility (Solar Farm) of solar equipment; and 2) a 220 kV Gen-tie Line. More specifically, the Solar Farm consists of 466 individual PV arrays, with each array occupying 2.4 to 2.8 ha (6 to 7 acres) and consisting of rows of PV panels supported on steel posts, a power conversion station, and a transformer. High-capacity 34-kV collection lines will transfer power output from the PV arrays to the onsite substation via overhead lines. The total acreage of the Project (including the Gen-tie Line) is 4,085 acres (1,653 ha). A chain-link fence topped with barbed wire encloses the entire Solar Farm, including support facilities (encompassing approximately 3,697 acres [1,496 ha]). The solar arrays cover 2,984 acres (1,208 ha).

In addition to the PV generating facility, other primary Project features include an operations and maintenance (O&M) building, visitor center, parking areas, access roads, fiber-optic lines, water wells, wastewater treatment facilities, an onsite electrical substation, and the 220 kV Gen-tie Line connecting the Project to the power grid.

Project features -- including solar panels, overhead electrical feeder and distribution lines, the Gen-tie Line, temporary retention basins, and the perimeter security fence -- pose potential mortality and injury risks to birds and bats. This BBCS focuses on permanent Project infrastructure elements including the solar panel arrays, perimeter fence and the Gen-tie Line. To minimize the threat of electrocution and collision, the Project's electrical distribution infrastructure is being built to avian-safe standards following Avian Power Line Interaction

Committee (APLIC) guidelines (APLIC 2005, 2006, 2012). Should birds or bats collide with the on-site distribution powerlines, injuries and fatalities will be documented during sampling of the solar arrays, as well as incidentally by Project staff during other activities.

3.0 SITE CHARACTERIZATION

The Project site is located in a relatively flat, previously undeveloped area of Chuckwalla Valley in eastern Riverside County. It is approximately 9.6 km (5.9 mi) north of Interstate 10 and the rural community of Desert Center, between the cities of Coachella to the west and Blythe to the east. Joshua Tree National Park wraps around the Project site to the west, north, and east; at its closest point, the Project is approximately 2.2 km (1.4 miles) southwest of the park boundary. Lake Tamarisk, a small golf-resort community, is approximately 6.4 km (four miles) to the south. The inactive Kaiser Eagle Mountain Mine is approximately 1.6 km (one mile) to the west.

The Project site is in the Colorado Desert Bioregion, which is the western extension of the Sonoran Desert of southern Arizona and northwestern Mexico. The Mojave Desert, which includes portions of Joshua Tree National Park, lies immediately north of the Project area. Chuckwalla Valley encompasses a series of alluvial fans that gently slope toward the southwest and southeast.

The 2011 FEIS prepared for the Project (BLM 2011a) describes the biological setting of the Project area. The FEIS included the results of biological surveys conducted in areas of potential impact associated with the Solar Farm, Gen-tie Line, Red Bluff Substation, and possible alternative sites (all collectively referred to as the Biological Study Area [BSA]). Before construction began on the Project, vegetation in the BSA consisted of Sonoran creosote (*Larrea tridentata*) bush scrub and desert dry wash woodland communities. To prepare for installation of the solar arrays, the Solar Farm site was disked and rolled, such that the Project landscape is now relatively flat and uniform, with vegetation re-establishing on the site. Stabilized sand sheets and pockets of sand dune deposits are located to the east of the Project area, but the Solar Farm site lacks wind-blown sand formations. Disturbed and developed areas that are either barren or dominated by ruderal vegetation occur primarily along roadsides. Agricultural areas, mostly fallow jojoba (*Simmondsia chinensis*) farms, are located southeast of the Project site.

Two temporary 0.4-ha (1-acre) ponds provided water during construction of the Project. One of the ponds was removed, and the second pond will be removed by the end of 2014. Several retention basins, which may hold water for some time after a storm event, are located within the Project’s perimeter security fence, along the western upstream boundary and on the southeastern downstream boundary. An open portion of the Colorado River Aqueduct runs around the north end of Chuckwalla Valley, from about six to 10 km (four to six miles) north of the Project site. An aquaculture facility, covering approximately 24 ha (60 acres), lies about three km (two miles) south of the Project site and contains perennially open water. The community of Lake Tamarisk includes homes, a golf course, and a small lake complex. The habitat structure and available water in this community routinely attract resident and migratory birds. All of these water features (when watered, in the case of the retention basins) can attract water-associated birds and shorebirds, either during migration stopover periods or in the course of local and intraregional movements.

4.0 CONSERVATION MEASURES IMPLEMENTED BEFORE AND DURING CONSTRUCTION

4.1 Pre-Siting Data Collection

In an effort to place the Project infrastructure in locations that would result in the least risk to populations of birds and bats, data on site characteristics and wildlife occurrence was collected and evaluated.

4.1.1 Coarse Site Assessment

In accordance with USFWS guidance, a siting evaluation of the solar farm site, Gen-tie line, and substation was completed. The Project conducted the equivalent of a Potential Impact Index (USFWS 2003) by evaluating suitability of the site proposed for development and estimating use of the site by selected wildlife species as an indicator of potential impact (USFWS 2010). Initial biological assessments conducted in 2007 recommended avoidance of Pinto Wash as potential habitat for special status species, and this assessment was supported during a site visit in 2010. Several modifications to Project design occurred that reduced the proposed Project footprint and moved it away from areas suspected to contain high-quality habitats for birds or bats. Alternative sites for the solar farm, Gen-tie line route, and substation were confirmed to occur outside any Important Bird Areas, Western Hemisphere Shorebird Reserve Network sites, and areas designated by the Convention on Wetlands of International Importance. The Gen-tie line and substation alternatives are located within the Chuckwalla Desert Wildlife Management Area and Critical Habitat Unit designated as management areas for desert tortoise.

4.1.2 Habitat Equivalency Analysis

A Habitat Equivalency Analysis (HEA) was conducted to quantify potential temporary disturbance versus permanent loss of habitat and to guide the habitat compensation process. The most significant step the Proponent took to promote wildlife conservation during this process was to coordinate with the BLM to determine suitability of habitat remaining within the solar application as area to be excluded from future development due to biological concerns.

4.1.3 Site-Specific Wildlife Surveys

As recommended by USFWS (2010), multiple survey techniques were used to collect baseline data on wildlife populations at the Project. Specific survey methods included:

- Diurnal point counts, conducted in April, May, and October 2010
- Raptor nest searches including golden eagle surveys (Pagel et al. 2010), conducted in April and May 2010

- Reconnaissance-level survey of Project components to determine which bat species could occur at the site
- Incidental data collection conducted during all biological surveys in 2010; additionally, incidental observations were collected over four years of activity at the Project

Thirty-eight passerines were recorded during baseline surveys. The only special-status species recorded were Brewer's sparrow (*Spizella breweri*), Costa's hummingbird (*Calypte costae*), and Le Conte's thrasher (*Toxostoma lecontei*). All three species are listed as USFWS Birds of Conservation Concern (BCC; USFWS 2008). Thirteen raptor species were documented, including California Species of Special Concern: burrowing owl (*Athene cunicularia*), loggerhead shrike (*Lanius ludovicianus*), and northern harrier (*Circus cyaneus*; CDFW 2008). Swainson's hawk (*Buteo swainsoni*) was also recorded, which is state-listed as threatened (CDFW 2014), along with federally-protected golden eagle (*Aquila chrysaetos;* BGEPA 1940). Surveys for bat habitat suggested that pallid bat (*Antrozous pallidus*), canyon bat (*Parastrellus hesperus*), hoary bat (*Lasiurus cinereus*), and California leaf-nosed bat (*Macrotus californicus*) could potentially occur at alternative sites given the habitat present. The list of most common species observed is found in Figure 2.

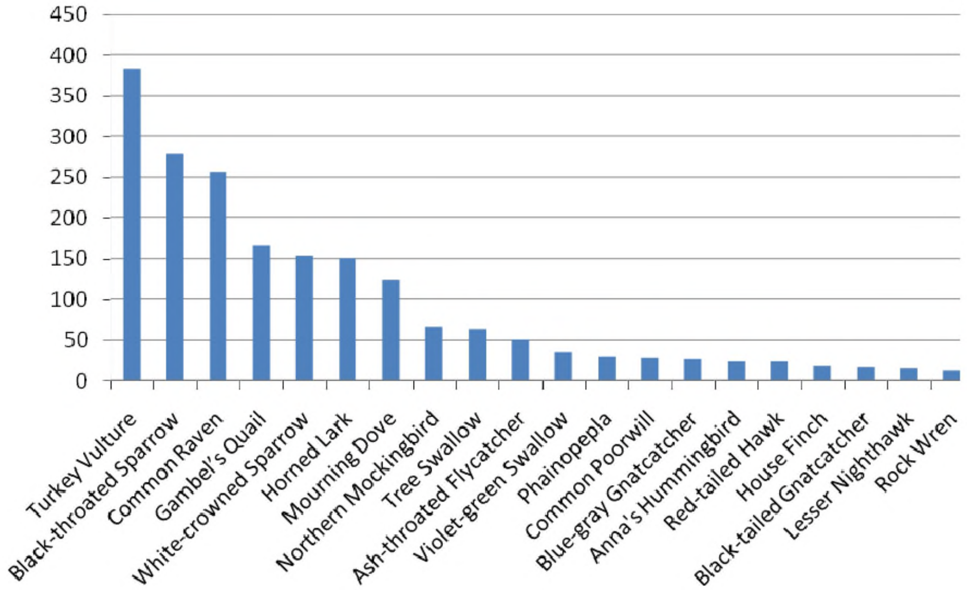

Figure 2. Avian species most frequently encountered during baseline surveys at Desert Sunlight Solar Farm Project, Riverside County, California.

5.0 CONSERVATION MEASURES

5.1 Project Siting

The process of siting the Project components included both macro- and micro-siting considerations. Macro-siting considerations occurred in 2007 during initial site surveys and were refined in 2008 after review of data. During this process, Pinto Wash and other larger areas of desert wash woodland were removed from Project consideration because they were deemed likely to support greater numbers of species or individuals than other habitats in the Right-of-Way area. Macro-siting considerations also included avoidance of:

- Locations with special status species and areas managed for the conservation of listed species
- Areas frequently used for daily bird and bat movements (e.g., areas between roosting and feeding sites)
- Breeding and wintering eagle use areas
- Known migration flyways for birds and bats
- Areas near known bat hibernacula, breeding, and maternity/nursery colonies
- Fragmentation of large, contiguous tracts of wildlife habitat

Micro-siting consideration for the Project components began in 2008 and continued as wildlife surveys were conducted and through informal meetings with the BLM, USFWS, and CDFW throughout the Project's planning process. Siting was also refined in response to concerns from the public and agencies involved in the process. Additional considerations of micro-siting included:

- Avoiding features that attract raptors (i.e., areas supporting tall perching structures including trees, utility poles, etc.)
- Avoiding features that attract migrant birds (e.g., water sources and vegetation)
- Minimizing the potential for enhancing habitats suitable for raptor prey such as rodents that would potentially attract raptors to the site.

5.2 Facility Design

Many conservation measures were incorporated into the design of Project facilities to reduce the potential effects of Project infrastructure on bird and bat populations, including:

- Avoidance of lattice-type structure or placing external ladders and platforms on towers to minimize perching and nesting
- Avoidance of meteorological towers with guy wires
- Minimal lighting and where lighting was necessary, facility lighting focused down ward to reduce sky illumination
- Power lines built in accordance with guidelines from the Avian Power Line Interaction Committee

- Minimal creation of new roads

5.3 Construction Phase Conservation Measures

Conservation measure implemented by the Project during construction included:

- Minimization of permanent disturbance area by minimizing creation of roads, avoidance of excessive clearing of vegetation, and grading whenever possible
- To the extent practicable, clearing of vegetation took place outside the bird breeding season. When not practicable, the Desert Sunlight communicated reasons to BLM, USFWS, and CDFG and provided a biological monitor to locate active nests, establish buffers, and stop construction when necessary when Project activity threatened a nest. Buffer distances of 100 m (330 ft), 152 m (500 ft), or one mile were used for active passerine, raptor, and golden eagle nests, respectively.
- Clearance surveys to locate and identify active nests or bat colonies
- Surveys for golden eagle nests conducted during each year there were construction activities within the nesting season
- Clearance surveys for burrowing owls completed in each construction unit and including a 150-m buffer area
- Mandatory site training for all construction personnel regarding avoidance of nests and bat colonies
- Following APLIC guidelines for overhead utilities
- Conducting construction activities in a manner consistent with reducing fire danger
- Trash promptly removed and disposed of to avoid creating attractions for birds or bats
- Established and implemented an Integrated Weed Management Plan (Ironwood Consulting 2010a)
- Used native species for seeding and planting during re-vegetation efforts

6.0 Incidental Avian Mortality Information during Construction and Early Operation

As of Oct 31, 2014, 198 avian and bat injuries or mortalities have been documented on-site during construction of the Project (Appendix A, First Solar 2014). Avian mortalities are being reported by construction workers and other staff incidental to their work activities. Consequently, the incidental nature of the data needs to be considered when evaluating the information reported to date. Data collected incidentally do not provide enough information to accurately quantify the scope of actual avian mortalities on a project site. However, these data can provide important information such as the composition of species which may be at risk in the future. In addition, the data provide insights into project features and types of injuries that may be associated with fatalities (U.S. Fish and Wildlife Service 2014). The majority of fatalities documented on the Project site are water-associated taxa (SPUT data). However, whether this pattern is representative of overall composition of fatalities at the Project remains to be determined through standardized monitoring.

7.0 POST-CONSTRUCTION MONITORING PLAN

This section outlines a standardized approach to document known and projected bird and bat fatalities and injuries, and to estimate seasonal and annual post-construction fatality rates associated with Project features. The Plan includes an approach to determine whether there are spatial patterns of fatality rates within the solar field (i.e., different fatality rates near panels on the edge of the solar arrays vs. the interior area of the arrays). The Plan is consistent with the Bird Monitoring and Avoidance Plan outlined in the Project's FEIS (BLM 2011a), and builds on standards and guidelines developed for the electric-utility and renewable-energy industries to quantify the risk of fatality and injury for birds and bats that may result from interactions with energy-related infrastructure (e.g., Anderson et al. 1999; APLIC 2005, 2006, 2012; California Energy Commission [CEC] and CDFG 2007; USFWS 2010, 2012). In particular, the Plan outlines a statistically sound spatial and temporal sampling plan, including protocols for independently estimating and correcting for quarterly searcher-efficiency and seasonal (i.e., at least quarterly) scavenger (avian and mammalian) removal rates. It describes specific data to be collected during scheduled carcass searches, protocols for handling any dead or injured birds and bats that are found, and procedures for reporting incidents to relevant government agencies. The study design is compatible with the BLM (2011b) Record of Decision requirement (MM-WIL-05) that, after the study is complete, Desert Sunlight will ultimately submit a description of the study design and monitoring results to peer-reviewed scientific journals.

7.1 Goals and Objectives

Primary goals of the post-construction fatality monitoring program are to:

1. Estimate overall annual avian fatality rate and species composition associated with the Project infrastructure. This estimate will include mortality associated with solar arrays, overhead lines including the Gen-tie Line, perimeter fence and other features of the Project that may result in injury and fatality.
2. Determine whether there are spatial and temporal/seasonal patterns of mortality associated with project infrastructure (e.g., different fatality rates near panels on the edge of the arrays vs. the interior area of the arrays).
3. Provide information that will assist the BLM in consultation with the USFWS in understanding which species and potentially which regional populations are at risk.

4. Collect data in such a way that the BLM in consultation with the USFWS may make comparisons with other solar sites.

These goals are structured in a way that provides information on seasonal differences in fatality rates, and information about which taxonomic groups are most vulnerable. Fatality estimates will be adjusted to address carcass persistence and searcher efficiency as they change through seasons. Additionally, carcass persistence trials will inform search intervals.

Consistent with the above goals, the specific objectives of this Plan are as follows:

2. Conduct fatality searches for a minimum of 2 years according to a spatial and temporal sampling plan that provides representative and statistically sound coverage of the solar arrays, consistent with monitoring required of other industries. The need for additional monitoring beyond the second year will depend on an evaluation of the survey results from the first 2 years to determine if the goals of the monitoring program have been met (see Section 10.0, Adaptive Management). The need to extend the monitoring period will be determined by the BLM in consultation with the USFWS. To the extent possible, standardized monitoring, as approved by the BLM in consultation with the USFWS, will commence within 30 days of 1) date a final BBCS has been approved, and 2) the commercial operation delivery (COD) date (anticipated January 2015). Implementation of any agency required pre-monitoring meetings, training and searcher efficiency/carcass removal trials may extend the start of monitoring beyond 30 days after the BBCS is deemed final.
3. Conduct statistically sound, seasonal assessments to quantify and evaluate carcass removal rates (i.e., carcass removal, destruction including dismemberment, or burial in sand due to scavengers, decay, or other abiotic [e.g., wind] or human [e.g., vehicle activity] factors) and support calculation of adjusted fatality rates that account for variation in carcass removal rates by season and carcass type/size classes. These assessments will also be used to guide search intervals.
4. Use current, scientifically validated and accepted methods for calculating fatality rates adjusted for searcher-efficiency, carcass removal rates, and spatial and temporal sampling intensity. At present, the best methods are distance sampling combined with searcher efficiency and carcass removal bias adjustments and a fatality estimator such as the Shoenfeld (2004) or Huso (2012) estimators, but it should be noted that fatality estimation is an area of active research and ‘best methods’ are changing rapidly. Therefore, as data are collected, adaptive management of the study design and monitoring protocol may be necessary and will follow the process in Section 10.0.
5. Summarize the species composition of fatalities according to taxonomic family, and ecological guild (e.g., raptors, water-associated birds, passerines, etc.) to aid in understanding species or groups at risk.
6. To the extent possible, summarize the composition of fatalities according to their likely propensity to collide with project components during the day vs. during the night based on known migratory patterns for the particular species.

7. Aid in identifying potential fatality causes and correlates by including additional information that is readily available beyond that which is under the SPUT such as the weight of fresh whole birds, or summaries of preceding weather conditions which would have made migration likely (e.g., low pressure systems moving cross continent to the north of the project area, followed by periods of high pressure systems).
8. Data summaries, and accompanying raw data, and any GIS shapefiles will be reported to the BLM with each seasonal report.

7.2 Monitoring Methods

A monitoring program will be implemented for at least 2 years post-construction as specified below. Survey results and analysis will inform adaptive management decisions regarding any additional appropriate and practicable BBCMs to avoid, minimize, and/or mitigate for observed impacts.

7.2.1 Post-Construction Monitoring of Solar Arrays

The fundamental characteristics of a sampling program designed to produce valid estimates of fatality rates for a solar farm (including the number of arrays to be searched, the search interval, the seasonal extent of coverage, and the number of years of sampling) are determined based on several factors. These factors include the questions of interest; the species of interest (e.g., resident, migratory, and/or wintering species) in the Project area, desired precision, best estimates of carcass-removal rates, searcher efficiency, the Project size and layout, and other relevant environmental (i.e., seasonal patterns), landscape, and habitat characteristics.

The following hierarchical terminology is useful for describing the spatial and temporal sampling design used to monitor solar arrays:

1) **Panel Cartridge:** An engineered assembly of solar panels installed as a single unit (approximately 2.5 x 2.9 meters [m; 8.2 x 9.5 feet (ft)]).
2) **Row:** A collection of panel cartridges arrayed side-by-side on a common, linear support structure (variable lengths ranging from approximately 71 to 142 m [232 to 464 ft]).
3) **Section or Subarray:** A collection of usually 20 commonly energized rows that represent one quarter of a typical array; dimensions (on the order of 71 x 84 m [232 x 274 ft]) are mostly uniform within blocks, but vary slightly among blocks; in most cases, structurally continuous rows span sections of two adjacent arrays.
4) **Array:** A collection of four sections connected to a common power converter station (PCS) and transformer, encompassing 2.4–2.8 ha (5.9-6.9 ac), depending on subsection dimensions and spacing between subsections (i.e., 466 total units in the Solar Farm).
5) **Block:** Collections of commonly energized arrays (20 blocks, each composed of 11–32 arrays).

7.2.2 Survey Strategy

Sampling strategies used in carcass searches have typically involved transect sampling, whereby searchers walk or drive along pre-defined transects and search for carcasses in a swath where width depends on visibility, target taxa, and other factors. The layout of PV facilities presents problems for a transect-sampling approach because rows of panels are close together (i.e., less than 5 m [16 ft] at the Project). Because the panels are mounted off-horizontal, a searcher walking or driving a transect between two rows can only effectively search one side of the transect (a 2.5-m [8.2-ft] swath), and the other side is obscured by the edge of a PV cartridge. However, traveling perpendicular to panel rows along the edges of the rows allows observers to see a greater distance of the ground beneath the panels. Surveyors will walk or drive the lines in air-conditioned vehicles. Should driving surveys be used, searcher efficiency trials will be conducted prior to implementation; results will be submitted and evaluated by the BLM and FWS within 2-weeks of completion of the trials to determine if conducting surveys using vehicles is acceptable. Other accommodations may be required to enable completion of surveys during high temperatures, such as shifting surveys to dawn and dusk.

The layout of PV facilities is well-suited to a distance-sampling approach. Distance sampling involves searching a transect line and assumes that searcher efficiency decreases (possibly dramatically) as a function of distance from the observer, and is ideally suited to situations in which animals (or carcasses) are sparsely distributed across a landscape (Buckland et al. 1993). The landscape at the Project is flat and relatively clear of vegetation, which should support a distance sampling design.

Distance sampling adjusts carcass counts for variable searcher efficiency by accounting for the *effective* area searched along a transect. Effective area is the total area searched multiplied by the average probability of detection in the searched area. As a highly simplified example, if a searcher walks a 10-m long transect line and detects 90% of all carcasses within 10-m of the line, and 60% of carcasses that are 10 to 20 m (33 to 66 ft) from the line, then the effective area between zero and 10 m would be $10\,m \times 10\,m \times 0.9 = 90\,m^2$ and the effective area searched between 10 and 20 m would be $10\,m \times 10\,m \times 0.6 = 60\,m^2$. For the total 10 by 20-m area searched, the adjustment factor would be $\frac{90\,m^2 + 60\,m^2}{100\,m^2 + 100\,m^2} = 0.75$. In practice, searcher efficiency is modeled as a continuous function of distance, and the detection function is estimated from the carcass data (as opposed to a bias trial). The searcher efficiency bias trials can be used to augment carcass data for the detection function. If the detection function calculated from the bias trials differs from the detection function calculated from the carcass data, this suggests non-random distribution of carcasses within the arrays, and simultaneously provides an adjustment factor to account for non-random distribution of carcasses. Preliminary data from the California Valley Solar Ranch (CVSR) suggests that non-random carcass distribution may not be a problem at PV solar facilities (H.T. Harvey and Associates 2014). One advantage to a data-driven detection function is that it is not necessary to specify a transect width: the detection function includes information about the distance at which searcher efficiency drops to zero. The detection function is used to determine the overall probability of detection as well as to inform the approximate effective view shed of non-zero detection probability for observers.

7.2.3 Spatial Sampling Design

The sampling design is intended to follow to the USFWS Land-Based Wind Energy Guidelines (2012), which states that “the carcass searching protocol should be adequate to answer applicable Tier 4 questions at an appropriate level of precision to make *general* conclusions about the project*, and is not intended to provide highly precise measurements of fatalities*” (p. 45; emphasis added). Under the proposed sampling plan, precision is expected to vary based on carcass detectability: less precision is expected for estimates of small-bird fatality compared to estimates of large-bird fatality. However, monitoring programs at two other PV solar facilities (CVSR and Topaz) suggest that the level of impact for small birds due to PV was not very extensive, and was similar in composition and rates than what was found on control plots for passerines.

The sampling design is based on a statistical precision analysis using data from CVSR, as well as a simulation-based analysis that was informed by searcher efficiency and carcass removal rates in the Mojave desert region (Appendix B). Sampling effort that includes 20% of the solar arrays is expected to produce a reasonable coefficient of variation (CV = 100% * standard deviation / mean) (~20%) if fatality rates are greater than 1.0 fatality / MW / year, and the search interval is at most 21 days. This level of precision is generally considered adequate for answering the primary questions of interest in fatality monitoring studies (Strickland et al 2011).
Based on the simulation analyses, data from CVSR, consultation with relevant permitting and wildlife agencies, and consideration of the characteristics of this particular Project, sampling will encompass approximately 30% of the completed solar arrays as summarized in Table 1.

Table 1. Solar array sampling area characteristics.

Total area	1,208 ha
Proportion sampled	30%
Sampling unit	~2.6-ha spatial equivalent of 1 array
Number of sampling units (whole facility)	466
Migration season search interval (March 1 thru May 31, September 1 thru October 31)	7 days unless adjusted by BLM in consultation with the Wildlife agencies based on results carcass persistence trials.
Non-migration season search interval (June 1 thru August 31, November 1 through Feb 28)	21 days unless adjusted by BLM in consultation with the Wildlife agencies based on results of carcass persistence trials.
Anticipated surveys per year	31
Duration of sampling	Minimum of 2 years

Because both the layout of the solar arrays and the landscape of the Solar Farm (i.e., mostly flat and free of vegetation) are largely uniform, a relatively simple random sampling design is likely to be adequate for sampling the arrays. However, in the absence of data, a spatially balanced sampling design will be used. Because spatially balanced designs ensure that sample effort is distributed over the whole study area, they help to ensure that spatially organized trends in mortality–should they exist-- can be extracted from the data. The drivers of spatial variation in avian activity may be important to the statistical sampling design if avian use patterns affect the distribution of mortalities on the project site. As an example, factors that may affect avian use patterns include: 1) habitat variation around the Project site; 2) the possibility that distinct movement corridors variably concentrate birds over certain areas of the Project site (e.g., migrating or commuting water-associated birds); or 3) use of distribution lines (and other transmission line infrastructure) as roosting sites. Distribution lines within the solar field may also pose a collision risk to birds. To achieve spatially balanced sampling, the site will be divided into 10 approximately equal-sized sampling areas and sampling will be stratified among those areas. Sampling will also be stratified proportionally among areas with distribution lines and those without.

The sampling units for the surveys consist of areas equivalent in size to a single array, but because of the concatenation of panel rows across arrays, they may include conjoined sections from multiple individual arrays (Figure 3). Within sampling areas, individual sampling units will be randomly selected to compose a 30% sample (± 1–2%).

Observers will survey sampling units from the outer edges of collections of continuous solar panel rows and scanning between each row for fatalities, with each side-specific survey covering half the width of the sampling unit (Figures 3 and 4). Surveys will occur along roadways that run approximately north–south (consistent with the “Bio Blitz” report; USFWS

2013) through the middle of most arrays and along the outer edges of some arrays. Most sampling units consist of combined array sections from four adjacent arrays. In most cases, the four sections run together both north to south and east to west, forming a continuous block composed of 40 continuous panel rows that are approximately 140 m- (460-ft) long. In these cases, two north-south routes will comprise the sampling-unit survey, with each route involving scanning across a maximum of 70 m (230 ft; Figure 3). Other sampling units have an additional roadway and powerline corridor running through the middle, such that the sampling unit consists of two subsections, each composed of 40 panel rows that are approximately 70 m long. In these cases, four north-south routes will comprise the sampling unit survey, with each route involving a maximum scanning distance of 35 m (115 ft) covering half the width of a subsection (Figure 3). For a few other sampling units with different layouts along the perimeter of the Solar Farm, the analysis will need to take into account the potentially different row lengths. Distance sampling and resulting data will be used to calculate detectability curves to calculate the average detection probabilities, and taking into account the potential for different detection curves depending on the direction of the survey viewshed.

Given the results of an initial detectability field trial (see below), the expectation is that effective sampling for larger birds (1000+ grams) will extend the full width of all sampling units, whether composed of 140-m or 70-m long panel rows. For smaller and possibly medium sized birds (0-100 grams and 101-999 grams) and bats, however, effective sampling is expected to be constrained to less than the maximum viewing distance. Density estimation using distance sampling techniques is easier, and can be accomplished with greater precision if the data are truncated at a distance beyond which the probability of detection is low (Buckland et al. 1993). Accordingly, data will be truncated and the density of carcasses in the effective search area will be used to calculate the density of carcasses in the whole solar facility.

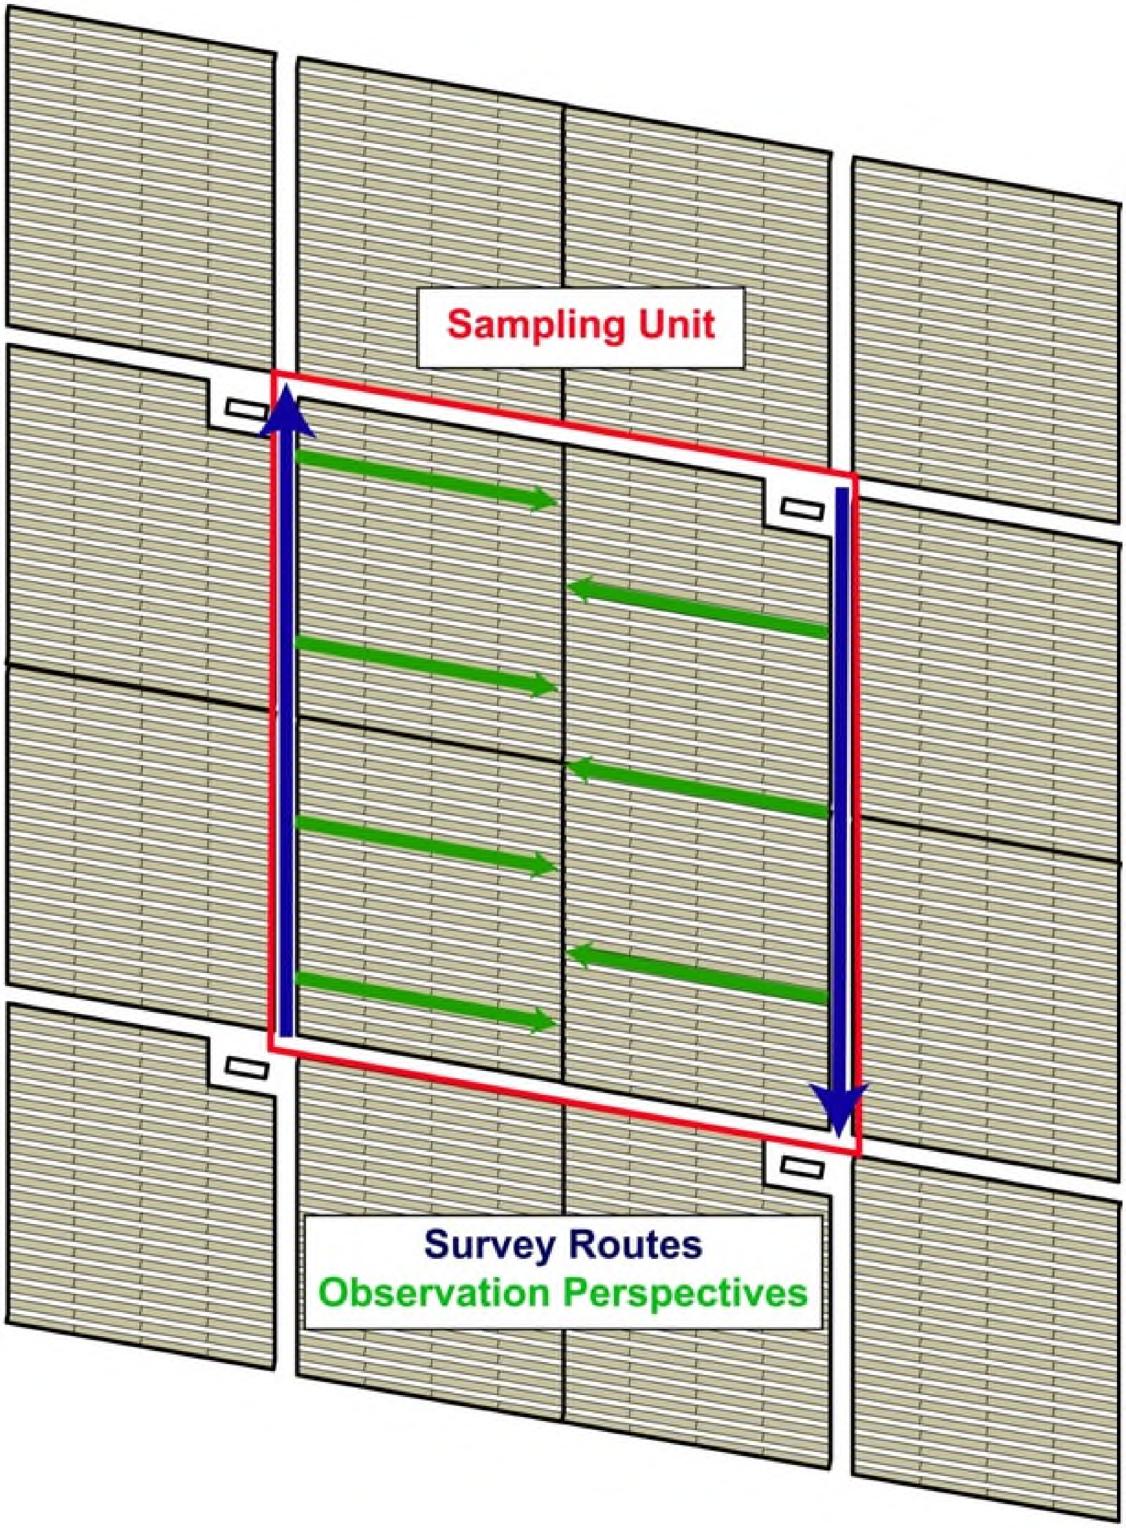

Figure 3. Illustration of a typical sampling unit and perimeter survey with travel routes and search areas ('observation perspectives').

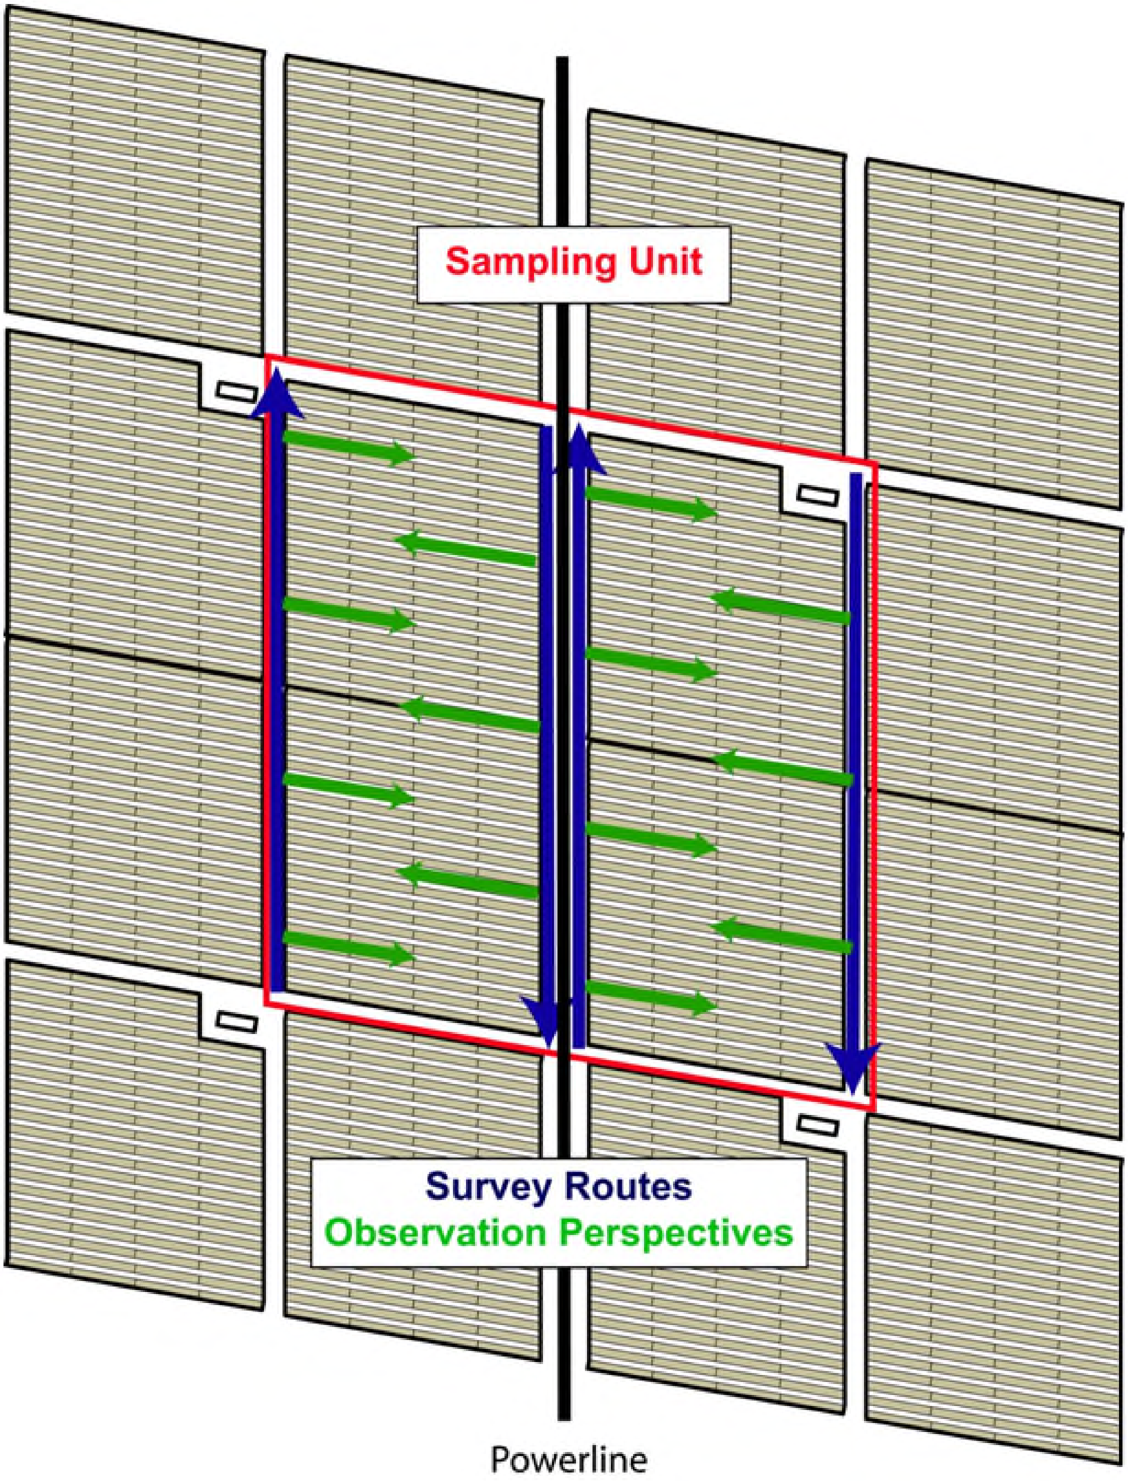

Figure 4. Illustration of a sampling unit survey including a distribution powerline with travel routes and search areas ('observation perspectives').

The perimeter-only survey design reflects two concerns: 1) minimizing movement between rows of solar panels. Because the area between electrified panel rows is an area of elevated risk, best practices dictate that personnel do not enter elevated risk zones unnecessarily; and 2) achieving an effective balance between logistic efficiency and sampling rigor given the constraints of transect spacing due to the width of panel rows. In support of the latter objective, a field trial was conducted to evaluate the ability of observers to detect carcasses of different types and sizes based on perimeter-only surveys that did not require walking between the rows of panels (H.T. Harvey and Associates 2013c). The field-trial surveys involved walking along the north-south edges of array sections perpendicular to the rows of panels and using naked-eye and binocular-aided scanning to search for placed carcasses of five non-native bird species, ranging in size from small house sparrows (*Passer domesticus*) to large ring-necked pheasants (*Phasianus colchicus*).

The field trial confirmed that, given the relatively flat, sandy, and uncluttered substrate that characterizes most of this solar facility, relatively large carcasses, such as rock pigeons (*Columba livia*) and pheasants, can be reliably detected (average detection probability over a 70–m wide transect > 0.75; Figure 5) using perimeter-only surveys, even when the continuous span of the solar-panel rows is 140 m, which applies across most of the facility. For smaller carcasses up to the size of small quail (*Coturnix japonica* in this case), however, detection probabilities will be much more strongly a function of distance (average detection probability over a 70–m wide transect > 0.35; Figure 5). Distance sampling is well-equipped to estimate population sizes, even when the detection function indicates a rapid decay in detectability with distance (Buckland et al. 1993).

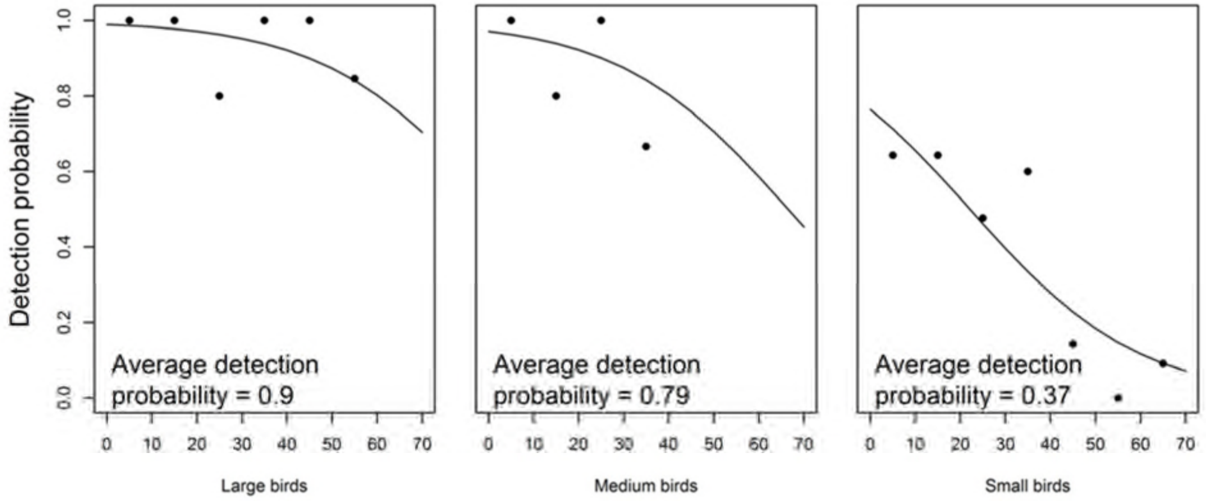

Figure 5. Logistic regression lines were fitted to detection data from the distance sampling trials at Desert Sunlight (HT Harvey 2013c). Data were binned into 10-m intervals prior to analysis. Fitted regression lines and observed proportions are shown. The fit for medium birds may be unreliable due to sparse data, but is probably intermediate between the fits for large and small birds.

Not being able to detect most small to many medium-sized carcasses over a substantial portion of the solar facility would comprise a problematic bias if the probability of carcass occurrence was non-random within arrays (i.e., within sample units). In other words, the bias would create a problem for achieving representative sampling if the probability of mortality due to panel collisions varied in some predictable fashion relative to the distance from array edges, or if there was a tendency for fatalities to be clustered in the interior of the panel areas. Whether or not such conditions may apply to this facility is currently unknown; however, initial post-construction monitoring at another large photovoltaic solar facility in central California has not demonstrated any particular spatial bias in the distribution of fatalities documented there (H.T. Harvey and Associates 2014).

On this basis, fatality sampling will proceed using distance-sampling survey techniques and analytical methods, which include estimating and accounting for distance-related variation in the probability of detection based on the carcass data and bias trial data. In addition, searcher-efficiency trials that are tailored to include evaluating the influence of distance on the probability of detection will be conducted to assess and adjust for the possibility of a spatial bias in the distribution of fatalities. This can be accomplished by comparing the detection function derived from independent searcher-efficiency trials with the detection function derived from the actual fatality data (as it is calculated based on standard distance-sampling techniques). If the two independently derived functions suggest divergent relationships between distance and the probability of detection, the pattern of divergence between them can be used to adjust results of the distance-sampling-based fatality estimate

7.2.4 Temporal Sampling Design

The appropriate frequency of fatality surveys depends on the species of interest and average carcass persistence times (Smallwood 2007, Strickland et al. 2011, USFWS 2012). Large raptors tend to persist and remain detectable for extended periods (weeks to months) due to low scavenging rates and relatively slow decay rates. If only large species were of interest, extended search intervals of 30–45 days might be appropriate; however, smaller birds and bats typically disappear at much faster rates, so shorter search intervals are required to ensure effective documentation of fatality rates among these species.

Publically accessible data from three wind-energy studies in the nearby Mojave Desert region of California and western Arizona provide additional, relevant insight (Chatfield et al. 2009, 2010; Thompson and Bay 2012). These studies recorded average persistence times of 17.5–46.8 days for large birds (average 29.0 days, median 22.6 days) and from 5.6–17.4 days (average 9.9 days, median 6.5 days) for small birds. If the median carcass-persistence time for small and medium birds and bats on the Project site is low a 7-day search interval may be required to effectively document fatality rates for small birds and bats. If, however, median small-bird and bat carcass-persistence rates are greater than 7 days, then a longer search interval may be more appropriate. The initial indications of rapid scavenging by ravens at the Project site suggested that a shorter search interval may be needed to provide precise fatality estimates for small bird and bat carcasses. Later data from Corvus (2014) suggests that there is a period of rapid initial removal, particularly for small and medium carcasses with 50% of carcasses in these size classes removed in 8 and 5 days, respectively. Overall, mean carcass persistence in May and June was greater than 10 days for any size of carcass, and greater than 24 days for large carcasses.

Based on these considerations and preliminary data, and based on the simulation analyses discussed previously, the search interval for fatality monitoring will be variable depending on season (Table 2). Searches will be conducted every 7 days during standard spring and fall migration periods (March 1 – May 31, and September 1 – October 31), and every 21 days during summer and winter (June 1 to August 31, and November 1 to February 28/29). After the first 6 months of fatality monitoring and concurrent carcass-removal trials (see below) have been conducted, the search interval may be adjusted based on estimates of carcass persistence. Some migration for some species may occur outside these periods and this will be considered when evaluating the data regarding timing of mortality for species.

Adjusting fatality counts for carcass removal works best when the search interval remains constant through time (Huso 2010); however, within survey periods, season-specific estimates of carcass persistence can be calculated and incorporated in the overall estimation process when variable search intervals are used in different seasons (Shoenfeld 2004; Huso 2010, 2012; and other estimators all have facility to accommodate season-specific estimates). In addition, survey schedules will ensure that fatality surveys are evenly spaced in time to maximize detection of potential, unusual fatality events (Strickland et al. 2011). For these reasons, a standard schedule for completing the surveys will be developed and followed, such that some surveys will occur during most weeks of the year and all sampling units are surveyed on a regular schedule, as dictated by the season.

7.2.5 Survey and Data Collection Protocols

Fatality surveys will be conducted with the observers striving for a consistent pace/speed and approach, and a uniform search effort throughout the search. Searchers will use binoculars at their discretion to survey for carcasses between each row of panels. The Project has rigorous safety protocols in place that address heat and other safety issues. When a potential carcass is detected, the observer will immediately proceed down the row to confirm the detection and, if valid, fully document and bag it according to standard protocols (see below). Depending on the size and nature of the carcass, the observer will either immediately collect the carcass (smaller, easily collected and transported packages) or flag it for pick-up once the sampling-unit survey is completed (larger, messier, or otherwise complicated collections) or to identify it to species. All carcasses will be stored in freezers on-site until the BLM and FWS determine the ultimate disposition.

All bird and bat injuries and fatalities discovered during, or incidental to, the standard carcass surveys will be documented according to the requirements and standards reflected in the USFWS Avian Injury and Mortality Reporting Form. The form is a reporting requirement of the USFWS Special Utility (SPUT) Permit issued to the Project to authorize the handling of dead or injured birds. In addition, finds will be classified as a fatality according to standards commonly applied in California (Altamont Pass Monitoring Team 2007, CEC and CDFG 2007), which dictate that when only feathers are found, to be classified as a fatality, each find must include a feather spot of at least five tail feathers or two primaries within 5 m (16.4 ft) or less of each other, or a total of 10 feathers. Searchers will make their best attempt to classify feather spots by size according to the sizes or identifying features of the feathers. A separate fatality estimate will be made for feather spots for which size classification is impossible. Digital photographs will be taken to document all incidents, and when possible, plausible cause of death will be indicated on data sheets based on evidence (such as blood or fecal smears on solar panels, burns that may indicate electrocution or blunt trauma that may indicate collisions). All carcasses will be examined and where possible cause of death will be recorded (e.g. burns may indicate electrocution, and blunt trauma may indicate collisions). An avian biologist will make decisions on likely cause of death and this will be reviewed by the Biologist overseeing the program.

All fatalities will be assigned to a size class, a taxonomic family, and an ecological guild and weight categories (e.g., 0-100 grams; 101-999 grams; and 1000+ grams). Species will also be classified as resident, overwintering, or whether they are diurnal or nocturnal migrants (or both). It is necessary to know size classes to appropriately correct for searcher efficiency and scavenging, and information about taxonomic family, ecological guild, and time of day when active are relevant to the specific USFWS and project goals of the monitoring plan.

To ensure accurate documentation of the fatality locations, the observer will record the array number, Global Positioning System (GPS) coordinates in latitude/longitude of the carcass location using a handheld device accurate to ± 3 to 4 m (9.8 to 13.1 ft), and a measurement of the distance from the fatality location to the end of the panel row from which the carcass was detected. When an observer proceeds down panel rows to confirm and document detected fatalities, they may detect other fatalities that they did not observe based on the perimeter-only survey. Including such detections in the fatality estimate will confound estimation of fatality density based on application of standard distance-sampling analytical methodology. Therefore, all such supplementary detections will be classified as “incidental” finds (discussed further below). Carcasses that are found within standardized search areas but incidental to the distance sampling searches can be used as an additional validation of the detection functions: the detection function specifies the distribution of found carcasses, but it also specifies the distribution of missed carcasses, and incidentals should follow the latter distribution.

Data records for each survey will also include: 1) full first and last names of all relevant surveyors in case of future questions; 2) start and stop times for each individual sampling-unit survey; 3) a description of the weather conditions during each search; 4) a standardized description of the current habitat and visibility classes represented within each sampling unit; and 5) a description of any search-area access issues, if relevant. Data collected will also include all appropriate fields contained in the SPUT permit.

All personnel involved in implementing this Plan will be included as sub-permittees under the Project’s USFWS SPUT Permit, issued either to the Project or a consultant authorized by the Project. If the CDFW does not consider coverage under the USFWS SPUT permit sufficient, all personnel implementing this plan will also be covered under any applicable CDFW Scientific

Collecting Permit if provided and issued either to the Project or its consultant. Ideally, the relevant state and federal permits will allow fatalities discovered during the study to be removed from the field, stored on-site in a freezer, and used in searcher-efficiency and carcass-removal bias trials. Necessary exceptions will apply to all special-status species (see below). Otherwise, surveyors will place all discovered carcasses or body parts that are not of a special-status species and are not part of an ongoing bias trial in zip-locked plastic bags, clearly label each bag with the incident number, and deliver the bags for storage in the designated freezer at the Project facility.

4.2.6 Fence Line Monitoring

The perimeter fence is subject to inspections approximately once every 7 days during spring and fall migration, and approximately once every 21 days during winter and summer periods with intervals adjusted as necessary based on the carcass persistence trials. A searcher will drive the areas accessible by vehicle close to the inner perimeter of the fence, scanning for fatalities within an approximate 6-m strip transect centered on the fence. Some sections along the fence cannot be driven close to the fence line. The fence line along the western edge of the Project is drivable but the road is approximately 15 m away from the fence and the road and fence are separated by a drainage ditch. The fence along this section is currently covered with a tan tarp to block and trees and shrubs have been planted to reduce visibility of the project from the west. Additions of vegetation and the tarp likely reduce potential for bird collision with the fence. This section of the fence will be driven to document carcasses, but will not be included in adjusted fatality estimates because detection rates are expected to be low. A separate section of the fence in the southeastern corner of the Project cannot be driven because the eastern edge of the berm that bounded construction ponds is too narrow for a vehicle. In this case, the observer will stop at both north and south ends of the berm and use binoculars to search for carcasses. Finally, the road along a portion of the southwest fence line near the entrance gate is approximately 30 to 50 m from the road and is separated from the fence by an area that has recently undergone vegetation restoration. This area will be eliminated from sampling. Fatality rates estimated for sections of the fence that are sampled will be extrapolated to sections of the fence where the standard monitoring protocol cannot be used. Travel speed will be no greater than 5 miles per hour (8 kilometers per hour) while searching to ensure quality detection, and safety. Personnel conducting fence checks will document bird and bat injuries and fatalities discovered along the inner fence line. Injuries and fatalities along the fence line will be documented in the same manner as used for those discovered during the array carcass surveys, and will be reported to the USFWS and CDFW as part of the same overall reporting process. Searcher efficiency trials will be conducted along the inside of the fence in a similar fashion to the trials at the solar arrays. Carcass removal trials conducted at solar arrays will include areas near the inside of the fence as well.

4.2.7 Power Line Monitoring

Power lines are built to APLIC (2005, 2006, 2012) guidelines; however, there is still a collision risk for many bird species. Consequently, a 50% sample of the Gen-tie Line will be monitored every 7 days during spring and fall migration and approximately every 21 days during summer and winter with intervals adjusted as necessary based on the carcass persistence trials.

Searchers will drive or walk 50% of the Gen-tie Line during each visit, scanning for birds within 15 m from the line. Injuries and fatalities along the Gen-tie Line will be documented in the same manner as used for those discovered during the array carcass surveys, and will be reported to the USFWS and CDFW as part of the same overall reporting process.

Some overhead electrical feeder and distribution power lines are co-located within the solar arrays and these co-located power lines may be searched as part of the regular monitoring schedule at arrays. Fatalities that are determined to have been caused by the power lines (as determined by the nature of injuries) will be reported as such to the USFWS and CDFW as part of the same overall reporting process and included in overall fatality estimates. In addition, portions of the Gen-tie Line are co-located with third-party structures and facilities, including other transmission infrastructure and roadways and, therefore, the source of a particular fatality may not be attributable to the Project's facilities.

4.2.8 Clearance Surveys

Depending on when fatality surveys commence, a one-time clearance survey will be conducted beginning approximately 21 days before the first round of official surveys begins in all areas planned for survey (fence line, gen-tie sample areas and solar arrays). The purpose of this survey will be to clear the survey area of any accumulated carcasses that may be present. The sequence of clearance surveys will mirror the schedule for the first official survey to ensure that the interval between the clearance survey and the first standard survey is the same for all sampling units. This is necessary to ensure that carcasses detected during the first round of surveys represent only fatalities that occurred during a preceding interval equivalent to the search interval that will apply afterward. Carcasses that are missed during the clearance survey will cause an upward (conservative) bias in the fatality estimate. Additionally, some estimators (such as the Huso estimator described above) become biased if carcasses that are not detected during a trial are still available during subsequent trials. This 'bleed through' effect can be ameliorated by including only fresh carcasses in the fatality estimate, where 'fresh' means a carcass that has arrived since the previous search. Carcasses that cannot reliably be aged (probably most carcasses) will be assumed to be fresh; this will cause an upward (conservative) bias in the fatality estimate.

7.3 Bird Rescue

Surveyors will record any injured or rescued birds or bats located during surveys. Birds will be assessed by a qualified biologist to determine if it is appropriate to transport the individual to the nearest permitted rehabilitation facility for proper care, or to release them. Injured raptors will be handled only by experienced personnel and will be taken only to rehabilitation facilities that are permitted to handle raptors; this provision is particularly important for eagles. From the Project site, the closest rehabilitation facilities capable of handling all avian species are:

- Coachella Valley Wild Bird Center, 46500 Van Buren, Indio, California, 92201; Phone: 760-347-2647; Contact: Linda York, Executive Director; Hours of Operation: 9:00am-12:00pm, 7 days a week. http://coachellavalleywildbirdcenter.org/

- The Living Desert Zoo & Gardens, 47900 Portola Avenue, Palm Desert, California, 92260; Phone: 760-346-5694 x8 x1; Contact: Sheila Lindquist, North American Manager; Hours of operation: 8:00am-1:30pm (June-September), 9:00am-5:00pm (October-May), 7 days a week (closed Christmas Day). http://www.livingdesert.org/animals/wildlife-rehabilitation/
- Hope Wildlife Rescue, 18950 Consul Avenue, Corona, CA 92881; Phone: 951-279-3232; Contact: Bill Anderson or Cyndi Floreno; **must call first (this is a CA-licensed rehabilitator working out of a personal residence)**.
- All God's Creatures Wildlife Rescue & Rehabilitation, Chino Hills, CA; Phone: 909-393-1590; Contact: Lori Bayour; http://www.allgodscreatures.net/index.html; no address available, contact by phone.
- International Bird Rescue, Los Angeles Center, San Pedro, CA, 90731; Phone: 310-514-2573; Hours: 8:00am - 5:00pm.
- A list of wildlife rehabilitators maintained by California Department of Fish and Wildlife: http://www.dfg.ca.gov/wildlife/WIL/rehab/facilities.html
- The California Council for Wildlife Rehabilitators: http://www.ccwr.org/resources/rehabilitation-facilities-region-6.html

If stranded, but apparently uninjured, water-associated birds are discovered at any time during surveys, the surveyor will take immediate steps to notify an on-call biologist, and assist with efforts to secure the bird and have it transferred as expediently as possible to Lake Tamarisk for release into the water. Injured water-associated birds may be taken to International Bird Rescue, which specializes in the care and rehabilitation of water-associated birds. If a mass event involving many such birds is observed, the surveyor will immediately notify on-call biologist or other biological personnel working on the site about the details and request their assistance identifying injured versus non-injured birds and transporting injured birds to the nearest rehabilitation facility. International Bird Rescue can also assist with mass stranding events. Rehabilitation facilities should be compensated for the costs associated with each bird put under their care.

If a surveyor discovers a dead individual of a species that is fully protected by the state or federally or state-listed as threatened or endangered, and for which handling is not specifically authorized under the applicable salvage permits, he/she will collect data and photos as for any other fatality, but then flag the carcass to mark its location and leave it in place. If it has been confirmed as a federally listed species under the Endangered Species Act, the surveyor will immediately call a USFWS Office of Law Enforcement special agent to determine the appropriate follow-up action.

7.4 Searcher Efficiency Trials

Estimating searcher-efficiency (distance-related detection functions) is a standard component of the distance-sampling approach. Moreover, because estimating detection functions is applied to all survey data and can be organized to variably adjust in relation to covariates of interest (e.g., season, habitat, and carcass size classes), application of this approach will account for typical factors of interest for fatality studies (CEC and CDFG 2007, Huso 2010, Korner-Nievergelt et al. 2011, USFWS 2012, Smallwood 2013). In this case, independent searcher-efficiency trials per season will be conducted to help assess and adjust for potential spatial bias in the distribution of fatalities among arrays. Separate trials will be conducted to assess detection probability associated with fence and gen-tie line searches.

The desert landscape in which this Project is located generally changes little with the seasons, save for brief periods following winter and spring rains when floods may occur and blooming plants may flourish. A recent meta-analysis involving data from more than 70 wind-energy projects suggested that including habitat visibility class as a predictive variable generally eliminated any otherwise apparent seasonal effects on searcher efficiency (Smallwood 2013). Nevertheless, the supplementary searcher efficiency trials for this Project will be repeated seasonally (winter, spring, summer, and fall) and trials will be organized so that all search personnel participate in bias trials. Placement of trial specimens will be timed to limit the number of trial carcasses placed on the landscape at any one time (minimizing the chance of artificially attracting scavengers or, conversely, scavenger swamping; Smallwood 2007). This approach will also ensure that any new surveyors that join the crew participate in searcher efficiency trials. The trials will also be managed to ensure effective quantification of searcher efficiency in relation to predefined habitat visibility classes (low, medium, and high, if relevant), size classes of birds (small and large), and detection distance.

The bias-trial sample sizes required to produce precise, adjusted fatality estimates are not well established, in part because needs may vary substantially depending on actual project-specific searcher efficiency, carcass removal, and fatality rates. However, using searcher-efficiency trials to help evaluate the efficacy of perimeter-only surveys and the distance-sampling approach used in this investigation will require larger sample sizes to produce a sampling design that effectively accounts for distance as a key covariate of interest. In addition, if growth of new ruderal vegetation, or substrate heterogeneity caused by flood events, is sufficient to create a new visibility class under the arrays, the specimen numbers would need to increase to effectively account for this factor. It will also be necessary to ensure that the estimates of searcher efficiency encompass variation among multiple surveyors. The influence of individual surveyors will not be accounted for in a formal, statistical sense by including “surveyor” as a covariate in the estimation model; however, all surveyors will be tested similarly. Each surveyor will be exposed to multiple test specimens of each size class, and at similar repeated levels if testing in different habitat visibility classes is required. A minimum of 15 carcass samples per small size class, 10 for medium, and 5 for large is anticipated within the fence line, solar array, and gen-tie sampling areas per season. Searcher efficiency will be summarized for each individual searcher but to avoid needlessly inflating the variance of the estimate, individual searcher effects will not be included in the fatality estimation model.

Besides representing birds of different sizes, another important factor to consider in searcher-efficiency and carcass-removal trials is the bird species to use as trial specimens. Ideally, all carcasses used for both searcher-efficiency and carcass-removal trials should reflect the range of species likely to be encountered as fatalities in the Project area (CEC and CDFG 2007). Because obtaining sufficient samples of "natural" carcasses often is difficult, researchers frequently resort to using readily available, non-native surrogate species in bias trails; however, this practice may result in biased results when compared to studies that use only "natural" specimens (Smallwood 2007). For all bias trials, this program will maximize use of representative native or naturalized species authorized by permits, either found during the study or gathered elsewhere, as needed, and from diverse sources where possible, but all trial carcasses will be obtained and deployed in a manner that are consistent with applicable regulatory requirements.

Another factor that influences carcass detectability is how fresh and intact the carcass is (Smallwood 2007, 2013). If multiple pieces of a depredated or scavenged carcass are scattered over a modest area, in some cases the fatality may be more easily detected; however, detectability generally decreases when only remnants of a carcass are present, or when the carcass is aged and degraded. Nevertheless, in contrast to wind-energy projects, there is little expectation that this Project will cause injuries and fatalities that result in dismembered carcasses, so this factor is not expected to influence searcher-efficiency or carcass-removal rates (Smallwood 2013). Therefore, bias trials conducted in this study will involve primarily intact carcasses. The searcher-efficiency trial specimens may range from freshly thawed to partially decayed (i.e., selected, subject to availability, to mimic the range of carcass decay that typically accrues over 7-day periods).

A field supervisor or other technician not involved in the standard surveys will place the trial specimens and will recover any specimens missed by the surveyors. All trial specimens will be placed according to a sampling plan that randomly allocates carcasses of different sizes among survey plots and survey days within the assessment areas, but is stratified to ensure equitable representation of different surveyors, fence line vs. solar arrays vs. gen-tie and seasons. To minimize the possibility of unnecessarily attracting scavengers or, conversely, contributing to scavenger swamping, which could affect ongoing carcass-removal trials (Smallwood 2007, Smallwood et al. 2010), placement of searcher-efficiency trial specimens will be distributed throughout the year (appropriately organized to provide season-specific estimates with adequate samples to provide a robust estimate of searcher efficiency), with few specimens placed at any one time. Carcasses will be placed carefully to minimize disturbance of substrates that may bias carcass detection. Sample size and frequency of trials in the second year may be reduced if the TAG deems appropriate (see section 10.0).

All trial specimens will be inconspicuously marked with a piece of black electrical tape wrapped around one leg, in a manner that allows the surveyor to readily distinguish trial specimens from new fatalities, but without rendering the specimen unnaturally conspicuous (Smallwood 2007, USFWS 2012). To ensure a degree of "natural" placement, carcasses need to be represented by placing between rows of panels, under panels, near i-beams supporting the panels, or in the open. Therefore, carcasses will be tossed towards the designated, randomly chosen placement spot from a distance of three to six m. Documentation of each location will include GPS coordinates, notes about the substrate and carcass placement, and a digital photo of the placement location.

Surveyors will have only one opportunity to discover placed specimens. Any missed specimens will be recovered as quickly as possible after surveys have been completed in a given area, and after the surveyor(s) have become aware of the trial through discovery of one or more specimens. Some researchers have argued for leaving missed specimens in place to enable possible discovery in a subsequent survey and thereby mimic the natural situation in which “bleed-through” is possible (e.g., Smallwood 2013, Warren-Hicks et al. 2013; discussed further below). Although this approach may have merit in some situations, its potential value for this Project is offset by the need to avoid attracting ravens, which represent a threat to desert tortoises living in the area (Ironwood Consulting 2010b).

7.5 Carcass Persistence Trials

The degree to which carcasses persist on the landscape depends on a variety of factors reflecting seasonal variation in landscape/climatic conditions and the scavenger community. The composition and activity patterns of the scavenger community often vary seasonally as birds migrate, new juvenile birds and mammals join the local population, and mammalian scavengers variably hibernate or estivate. Seasonally variable climatic conditions also may contribute to variation in carcass decay and removal rates due to variation in temperatures, solar insolation, wind patterns, and the frequency of flooding events. Therefore, to ensure accurate treatment of this bias factor, carcass-persistence rates will be assessed on a quarterly or at least semi-annual basis during the first year that fatality surveys are conducted (CEC and CDFG 2007, USFWS 2012, Smallwood 2013), and during the second year as needed. It is also imperative that carcass-persistence trials effectively account for the influence of carcass type/size, given that persistence times may vary widely depending on the species and size class involved (Smallwood 2013).

To quantify carcass persistence, 15 small, 10 medium, and 5 large carcasses will be randomly placed and monitored within the solar arrays (including the fence line), and along 50% of the Gen-tie Line each season. A minimum of ½ of the carcasses in the solar arrays will be monitored, using motion-triggered, digital trail cameras (e.g., see Smallwood et al. 2010) while the remaining will be visited on foot, for 30 days or until the carcass has deteriorated to a point where it would no longer qualify as a documentable fatality. Some of the carcasses along the gen-tie line will be monitored with cameras if theft and vandalism concerns can be resolved. For carcasses not set up with cameras, the carcass will be visited once a day for the first 4 days, and then every 3 to 5 days until 30 days is reached. Fake cameras or cameras without bias trial carcasses will also be placed to avoid training ravens to recognize cameras as “feeding stations”. Periodic ground-based checking of carcasses also will occur to guard against misleading indicators of carcass removal, such as wind blowing the carcass out of the camera’s field of view. To minimize potential bias caused by scavenger swamping (Smallwood 2007, Smallwood et al. 2010), carcass-persistence specimens will be distributed across the entire Solar Farm, not just in areas subject to standard surveys, and new specimens will be placed every two to three weeks in small numbers. Sample size and frequency of trials in the second year may be reduced if the TAG deems appropriate.

Trial specimens will include only intact, fresh (i.e., estimated to be no more than one or two days old and not noticeably desiccated) bird carcasses that are either discovered during the study or are acquired from other sources after having been frozen immediately following death. If permits allow, preference will be to use carcasses of species that occur in the area. Surrogates, such as game birds and waterfowl, that are similar in size and appearance to species that occur in the area, will be obtained from commercial sources and used if necessary to meet the required sample sizes. However, domestic waterfowl or gamebirds that are white or brightly colored (e.g. male pheasants) will not be used. Scavenging rates for surrogates may be artificially high, at least when compared to raptors (Smallwood 2007, 2013) and may lead to conservative fatality estimates (i.e., an overestimate) for some taxa/groups.

To reduce possible biases related to leaving scent traces or visual cues that may unnecessarily alert potential scavengers, all carcasses used in carcass-persistence trials will be handled with latex gloves, and handling time will be minimized. All trial specimens will be inconspicuously marked with a small piece of green electrical tape wrapped around a leg to distinguish them from both unmarked fatalities and searcher-efficiency trial specimens.

Upon conclusion of the relevant monitoring period, each trial specimen will be classified into one of the following categories:

Intact: Whole and un-scavenged other than by insects

Scavenged/depredated: Carcass present but incomplete, dismembered, or flesh removed

Feather spot: Carcass scavenged and removed, but sufficient feathers remain to qualify as a fatality, as defined above

Removed: Not enough remains to be considered a fatality during standard surveys, as defined above

7.6 Estimating Adjusted Fatality Rates

The sampling design will enable calculation of fatality estimates adjusted for searcher-efficiency, carcass-removal rates, and proportion of area sampled. The adjustment for searcher efficiency will occur by virtue of applying standard methods for analyzing detection data collected using distance-sampling methods, with the data partitioned by season and standardized carcass size classes.

The fatality estimates will be adjusted for variation in carcass persistence, by applying seasonal and carcass-size-specific correction factors to the fatality estimates that have been adjusted for distance-related variation in the probability of detection.

The analytical approach used to calculate adjusted fatality estimates will be similar to that applied in cases where the fatality estimates are derived from strip transects.

For illustrative purposes, we summarize here the basic formulation of the Huso estimator, the first part of which pertains to fatality estimation for different strata, or groups. Essentially, the smallest group for which fatalities are estimated can be considered a stratum, with stratum *k* representing, for example, a set of similarly sized birds within a defined habitat visibility class. Note that strata should be defined to ensure minimum variance in detection probabilities within individual strata, whereas probabilities may vary considerably among strata (e.g., for small versus large birds, or in habitats of low versus high visibility). Depending on the circumstances, there can be strata based on species groups, size classes, seasons, habitats, and/or infrastructure types (also could conceivably model distance categories as another covariate).

For a particular stratum *k* for a given survey plot and search interval, fatality can be estimated as:

$$\hat{F}_k = \frac{c_k}{g_k},$$

where c_k is the number of observed carcasses and g_k is the probability of detecting a carcass. The detection probability *g* typically is the product of three variables: the probability of a carcass persisting (*r*), the probability of a carcass being observed given that it persists (*p*), and the effective proportion of the interval sampled (*v*):

$$\hat{g} = \hat{p} * \hat{r} * \hat{v}.$$

The probability of a carcass being observed given that it persists (i.e., searcher efficiency) is estimated as:

$$\hat{p} = \frac{number\_observed}{number\_available},$$

with data for calculating this metric derived from searcher-efficiency trials where known numbers of carcasses are distributed over the search area and carcass detection rates are quantified.

The probability of a carcass persisting is estimated as:

$$\hat{r} = \frac{\bar{t}(1-e^{-I/\bar{t}})}{I},$$

where $\bar{t}$ is the estimated mean carcass persistence time and I is estimated as:

$$I = \min(I_a, \tilde{I}),$$

where I_a is the minimum actual time between searches and $\tilde{I}$ is the effective search interval, defined as:

$$\tilde{I} = -\log(0.01) \cdot \bar{t}.$$

The effective proportion of the interval sampled is estimated as:

$$\hat{v} = \min(1, \tilde{I} / I_a).$$

For this investigation, the formulation for calculating $\hat{F}_j$ would differ from that outlined above, in that "c_k" would represent the estimated number of fatalities already adjusted for searcher efficiency, based on application of distance-sampling methodology, and then g_k would represent the product of only the estimated carcass persistence (r) and the effective proportion of the interval sampled (v). With this modification, the rest of the formulation would be similar.

For a given plot in search interval j, the adjusted total number of fatalities is calculated as:

$$\hat{F}_j = \sum_{k=1}^{K} \hat{F}_{jk},$$

where $\hat{F}_{jk}$ is the estimated number of fatalities within stratum k of search interval j.

Finally, the estimate of Project-wide total fatalities during a given search interval is estimated as:

$$\hat{F} = \frac{1}{a} \times \left(\sum_{i=1}^{n} \frac{1}{\pi_i} \sum_{j=1}^{J} \hat{F}_{ij} \right),$$

where $\hat{F}_{ij}$ is the number of fatalities on plot i in search interval j, a is the proportion of area that was searched and π_i represents a modified weight associated with an unequal probability sample (Huso 2010), and is the product of the probability of selecting plot i and the proportion of fatalities contained in plot i. The total number of search intervals is J, assuming that there is the same number of search intervals for each plot. In practice, one need not assume that J is constant, but presenting it this way simplifies the notation.

Adjusted fatality estimates for the Solar Farm will be expressed per unit area (e.g., acres and arrays) per year.

7.7 Incidental Mortality Documentation

Once post-construction fatality monitoring begins, all subsequent bird and bat injuries and fatalities detected incidental to the standardized, post-construction monitoring program will be classified as “incidental finds,” documented using similar procedures as are used for specimens discovered during the standardized surveys, and integrated with records from the standardized surveys for summary reporting and evaluation purposes. Incidental finds that occur outside of standard search areas will not be included in calculations of adjusted post-construction fatality estimates, but will be summarized within seasonal and annual reports (discussed below).

From a statistical standpoint, a bias will occur if carcasses that are found in standard search areas but not during standardized surveys are recorded and removed prior to the next search of that array. Per USFWS direction, and to be consistent with the raven management plan, these carcasses will be reported directly to an authorized Biologist. These incidental finds will be documented using the same procedures as those discovered during standardized surveys. Data from incidental finds within standardized search areas will be included in analyses to estimate mortality within the solar arrays to be conservative. Appropriate caveats can be included within the seasonal and annual reports to document the potential magnitude of any biases created by recovering these carcasses.

8.0 MINIMUM CREDENTIALS OF MONITORING PERSONNEL AND TRAINING

The fatality monitoring program will be overseen by an Avian Biologist approved by BLM in consultation with Wildlife agencies that has demonstrated the ability to accurately identify the species of birds and bats potentially impacted by the project. Additional Biologists will be approved by the BLM in consultation with the Wildlife agencies for the purpose of accurately identifying species of birds and bats potentially impacted by the project. The approved biologists will assist with fatality monitoring and will be available to respond to incidents at the Project that require expert assistance (e.g. uncertain species identification, possible listed species, or injuries) within 24 hours. In addition, a biologist (minimum of B.S. in wildlife sciences) will be on-site during days of standardized monitoring.

Monitoring personnel may include solar facility staff. Monitors will be trained in distance-sampling search methodology, correct identification and documentation of carcasses, implementation of carcass removal trials and notification of a rehabilitation center in the event of injured birds or bats. Only staff/technicians that are listed under the SPUT and CDFW Scientific Collecting Permits will be allowed to handle carcasses. Accurate identification of rare, special status species will be emphasized during training. All surveyors will have photo cards to classify specimens and will take photographs of all finds. All data collection will be standardized and the Approved Avian Biologist will decide which to report as survey observations; however, all observations that were not conclusive will be reported.

The trainer, curriculum and training materials for training of non-biologist personnel in monitoring methods will be approved by BLM in consultation with the Wildlife agencies and will be conducted by The Approved Avian Biologist prior to initiation of the study. Training materials may be augmented by wildlife agency input. Components of the training program will include:

- A classroom-based portion with lecture and handout materials, and photographic or specimen-based (if available) species identification;
- A field-based portion that allows trainees the opportunity to practice and receive feedback on conducting carcass searches and trials, identification of species, completing data forms, and following protocols for assessing and assisting injured birds and bats;
- Assessment of learning outcomes for each participant;
- A training log to be updated with each trainee's name and contact information upon successful completion of the course.

The Avian Biologist that will conduct the training will, minimally, have a master's degree in biological sciences, zoology, botany, ecology, or a related field, and at least one year of field experience with avian or bat research or monitoring in the region. All reference material should be maintained and provided to the agencies in the event that there are questions about species identification.

9.0 REPORTING

9.1 USFWS Bird Fatality/Injury Reporting Program

The Project will report all documented bird injuries and fatalities to the USFWS using the required Avian Injury and Mortality Reporting Form that is a reporting requirement of the USFWS SPUT Permit issued to the Project to authorize the handling of dead or injured birds. SPUT reporting will be submitted monthly or in accordance with the terms of the permit. Similar reporting to the CDFW will be accomplished as a condition of any relevant Scientific Collecting Permit that the CDFW may issue to authorize the handling of dead or injured birds under state law.

9.2 Incidental Bird Injury/Fatality Reporting

All injury and fatality incidents discovered outside of the standardized carcass surveys will be documented in the same manner as used for those discovered during the carcass surveys, and will be reported to the USFWS and CDFW as part of the SPUT process. Special status or listed species will also be handled in a way that is consistent with project-specific SPUT permit conditions. Additional details on reporting are found in the Desert Sunlight Wildlife Incident Reporting System (Appendix C).

9.3 Summary Reports

Seasonal electronic summaries of all biological monitoring activities will be submitted to BLM, USFWS, and CDFW throughout the monitoring period. After the fourth quarter of each year of monitoring, a biologist representing the Project will assist the Project in preparing and submitting to the CDFW, BLM, and USFWS an annual report that summarizes dates, durations, and results of all fatality monitoring conducted to date.

To address the specific objectives of the monitoring plan, summary reports will include overall fatality estimates with confidence intervals, and fatality estimates by season. In addition, to the extent possible, fatality rates will be estimated and reported for likely diurnal, and likely nocturnal species, and for ecological guilds of interest (e.g., raptors, water-associated birds, passerines). Summary reports will also include spatial analyses of the data that address whether fatalities are randomly distributed throughout the facility. All raw field notes, field data, photographs, and GIS data will be submitted to the agencies.

10.0 TECHNICAL ADVISORY GROUP AND ADAPTIVE MANAGEMENT

A Technical Advisory Group (TAG) will monitor Project activities, including fatality data, to provide recommendations to the BLM on the need for any adaptive management, including the adoption of avoidance and minimization measures and methods for assessing their effectiveness. The TAG will consist of resource specialists and project biologists from the BLM, USFWS, and CDFW. Persons with scientific expertise may be invited by TAG. In addition, representatives from the Project and the consultants involved in the conduct of the studies will attend and participate in meetings. The TAG will provide advice and recommendations, consistent with the principles below, to the BLM Authorized Officer on developing and implementing effective measures to monitor, avoid, minimize, and mitigate impacts to wildlife species and their habitats related to operations. The BLM Authorized Officer will evaluate any recommendations of the TAG, including discussions with Desert Sunlight concerning new measures or measures that are not completely detailed in this BBCS and make a decision on what measure(s) and monitoring to require for implementation.

A TAG Lead from the Project will be designated for the group whose duties will include disseminating Project data, including data on fatality events, setting up and moderating meetings, reviewing of fatality data, and documenting adaptive management recommendations for the Project. Because the Project occurs on BLM land and BLM is the federal decision-maker, BLM will provide a designated TAG Lead for the Project. It is the TAG Lead’s responsibility to coordinate meetings and involve all team members.

The guiding principles, duties, and responsibilities of the TAG include the following:

- The TAG is only an advisory group.

- Recommendations will be made based on best available science and existing approvals and permits to address specific issues resulting from the Project.
- Recommendations will generally be made by consensus. Where consensus cannot be reached, multiple recommendations will be put forth to the BLM for a final decision.
- Provide sufficient flexibility to adapt as more is learned about the Project as well as strategies to reduce avian impacts if warranted.
- Review results of fatality monitoring.
- In accordance with Mitigation Measure (MM) WIL-5 of the Project's Record of Decision (ROD), if BLM, in consultation with the Wildlife agencies, determine, based on post-construction monitoring, that bird mortality caused by solar facilities is substantial and is having potentially adverse impacts on special-status bird populations, the TAG may recommend adaptive management strategies such as installing additional bird flight diverters, alterations to project components that have been identified as key mortality features, or implementing other appropriate actions to address the relevant findings based on the data.
- Review annual report on status of compliance with mitigation measures and permit conditions and provide recommendations to the BLM Authorized Officer, as necessary.
- Evaluate effectiveness of implemented adaptive management strategies and provide the BLM Authorized Officer with recommendations based on findings.
- The TAG will terminate when the BLM Authorized Officer determines that it is no longer a necessary pathway in reducing avian and bat impacts.

The TAG shall hold the first meeting prior to commencement of post-construction monitoring to review any final details of the monitoring plan. Subsequent meetings will be held following each monitoring season and after the end of each annual monitoring cycle.

After the initial 3-month period, the TAG will review the findings for each monitoring season to determine if adjustments to the monitoring frequency are warranted based on carcass persistence trial results. Desert Sunlight and the agencies will also meet at the end of the second year of monitoring to determine if continued/focused monitoring is warranted. Continued/focused monitoring may be warranted if data indicate that bird mortality caused by solar facilities is substantial and is having potential adverse impacts on special-status bird populations or there are other special circumstances. Such monitoring will be designed to address specific concerns that are identified after review of the data.

Grand Total	198

Appendix B
Summary of Statistical Simulations for Experimental Design from CVSR

Recent statistical power and precision analyses conducted for another solar project being built roughly 193 km (120 miles) north of the Project site provides some guidance for developing a spatial sampling regime (TerraStat Consulting Group 2013). These simulations were based on projected sampling across an entire 392-MW solar thermal facility, so the results may not accurately reflect the expectation at facilities of different sizes or where sampling is constrained to smaller portions of a large facility; nevertheless, the general guidance they provide is useful. The simulation analyses were parameterized based on several wind-energy studies conducted in the Mojave Desert, and incorporated one of several well-studied mathematical approaches for estimating fatality rates adjusted for proportion of area sampled, search interval, searcher efficiency, and carcass persistence (Shoenfeld 2004). The power analyses assessed the effect of varying the proportion of area sampled from 1% to 30%, using search intervals of 7, 21, and 25 days, and simulating four hypothetical mortality rates (0.5, 1.0, 5.0, and 10 fatalities/MW/year), assuming exponentially distributed carcass removal rates with means of 7.4 or 21.8 days and searcher efficiencies of 0.55 and 0.69 for small and large birds, respectively. The simulation results indicated that the 90% confidence interval for the facility-wide fatality estimate narrowed as the survey area increased, as the search interval decreased, and as the simulated mortality rate increased. The coefficient of variation (CV: $100\% \times$) provides a way to evaluate the relative amount of imprecision in an estimate. The CV is useful because it doesn’t depend on the size of the estimate and so can be compared between large and small estimates. Larger values of CV are associated with estimates that are less precise: a CV of 100% indicates an estimate with a standard deviation that is equal to the mean. At all of the simulated mortality rates, and based on a 21-day search interval, the CV for the fatality estimates approached an asymptote once the proportion of area searched reached about 20%. In addition, at the 20% sample level, the CV for the fatality estimates was less than 25% for mortality rates that exceeded 1.0 fatality/MW/year. This level of precision generally is considered adequate for answering the primary questions of interest in such fatality studies (Strickland et al. 2011), and is consistent with guidance from the USFWS Land-Based Wind Energy Guidelines (2012), which states that “the carcass searching protocol should be adequate to answer applicable Tier 4 questions at an appropriate level of precision to make *general* conclusions about the project*, and is not intended to provide highly precise measurements of fatalities*” (p. 45; emphasis added). At the lowest simulated mortality rate, with a 21-day search interval, the coefficient of variation was above 50% at 20% of area sampled, which would be considered a marginal precision level for answering the questions of interest. From a practical standpoint, the importance of precision is diminished if impacts are low. For example, if the take estimate is 0.1 bird per year with 200% CV, this suggests a 90% confidence interval of about (0, 0.4), or a range of less than half a bird per year. On the other hand, if the take estimate is 100 birds per year and the CV is 20%, the 90% confidence interval is (61, 139), or a range of 78 birds per year.

At the lower simulated mortality rates, increasing the proportion of area sampled from 20% to 30% had less impact on the precision compared to decreasing the search interval from 21 days to 7 days. For the two highest simulated mortality rates, however, varying the search interval had less effect on the precision of the adjusted fatality estimates, whether based on 20% or 30% of area sampled, with the CVs remaining between about 8% - 19%. At the 1.0

fatality/MW/year mortality rate with 20% of the area sampled, the CV increased from about 25% with a 7-day search interval to about 40% with a 21-day search interval. At the 0.5 fatalities/MW/year mortality rate with 20% of the area sampled, the relevant change in the CV was from 37% to 57%.

Analysis of data from the CVSR in San Luis Obispo County, California (H.T. Harvey and Associates 2014) corroborates the simulation results. The CVSR is a recently completed 250-MW facility comprising nine discrete photovoltaic solar arrays, which collectively cover approximately 642 ha (1,586 acres) of primarily degraded annual grassland. Beginning in fall 2012, 100% of two arrays were surveyed weekly for bird and bat fatalities using 50-foot transects for large birds and 20-foot transects for bats and small birds. A total of 175 avian fatalities were found during standardized surveys in the two arrays over 10 months. The Huso (2010) estimator was used to estimate the number of fatalities based on documented fatalities adjusted for searcher efficiency and carcass persistence.

Two methods were used to evaluate the potential effects of reduced search area on fatality estimates at CVSR. Spatial clustering of fatalities was evaluated using Global Moran’s I index, which indicates whether objects are clumped, uniform, or random in their spatial distribution (ESRI ArcInfo 10.0, geographic statistical toolbox). Spatial clumping of fatalities within the individual arrays would introduce additional uncertainty into the fatality estimates if sampling covered considerably less than 100% of the survey area. The second method involved resampling the observed fatality data to generate distributions of fatality estimates that would have resulted from searching less than 100% of the study area. Sample sizes varied from one sample unit up to the total number of sample units in the study area (180). (At CVSR, a sample unit was one “tracker unit,” a group of 18 rows of solar panels covering approximately 0.34 ha (0.85 acres); sample units at CVSR were about a quarter the size of the proposed sample units at Desert Sunlight.) For each sample size, 2,000 simulated datasets were generated from the original data. Then, for each simulated dataset, the total number of fatalities for the study area was calculated by scaling the sample count according to the proportion of area represented in the sample. This procedure resulted in a distribution of possible fatality estimates for each level of area sampled. Based on these distributions, means, 90% confidence intervals (CI), and CVs were calculated for each sample size to evaluate the effect of sampling variation on the magnitude and precision of the fatality estimates.

The geospatial analysis indicated that the distribution of fatalities in the two, 100% searched arrays did not differ significantly from a random distribution (H.T. Harvey and Associates 2014). Results of the resampling analysis indicated that the mean fatality estimates and the 90% CIs for those estimates stabilized at about 20% of area sampled (Figure 1). Examined in a different way, the results indicated that the CVs of the sample distributions declined with increasing sample size and that, again beyond about 20% of area sampled, further increases in area sampled resulted in only small increases in precision (Figure 2). Moreover, at the 20% sample level, the CV for the fatality estimates was well below 20%, which is a level of precision that is considered adequate for answering the primary questions of interest in such fatality studies (Strickland et al. 2011, USFWS 2012). With regard to applying these results to other sites, it is important to note that the results may be sensitive to: 1) the relative proportions of large and small birds represented in the fatality sample, which were combined for this analysis; 2) the number and distribution of fatalities across the site; and 3) the influence of variation in searcher efficiency and carcass persistence.

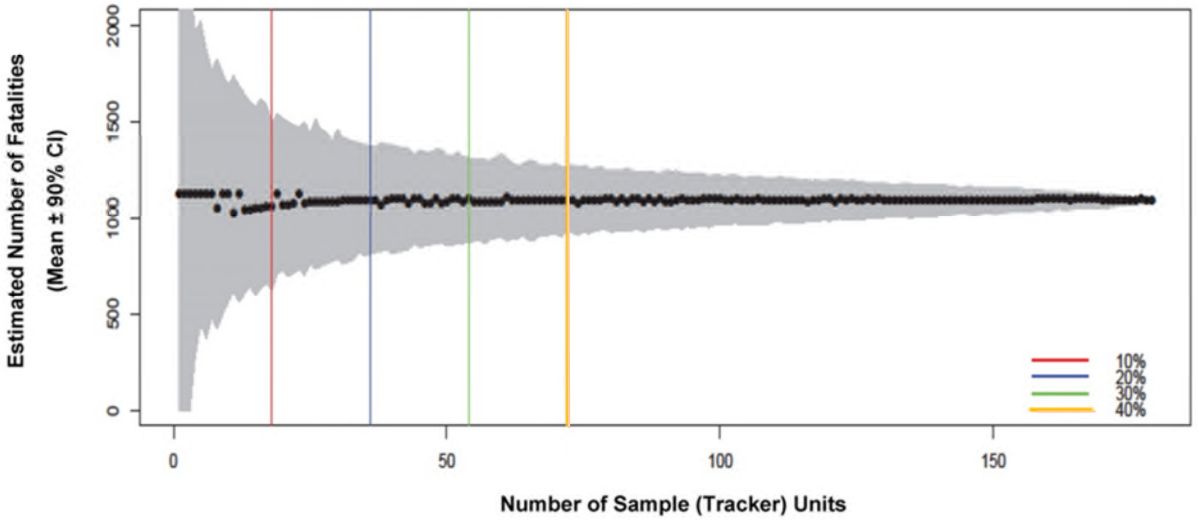

Figure 1. Resampling results from the California Valley Solar Ranch illustrating how the accuracy and precision of fatality estimates and varies with proportion of area sampled.

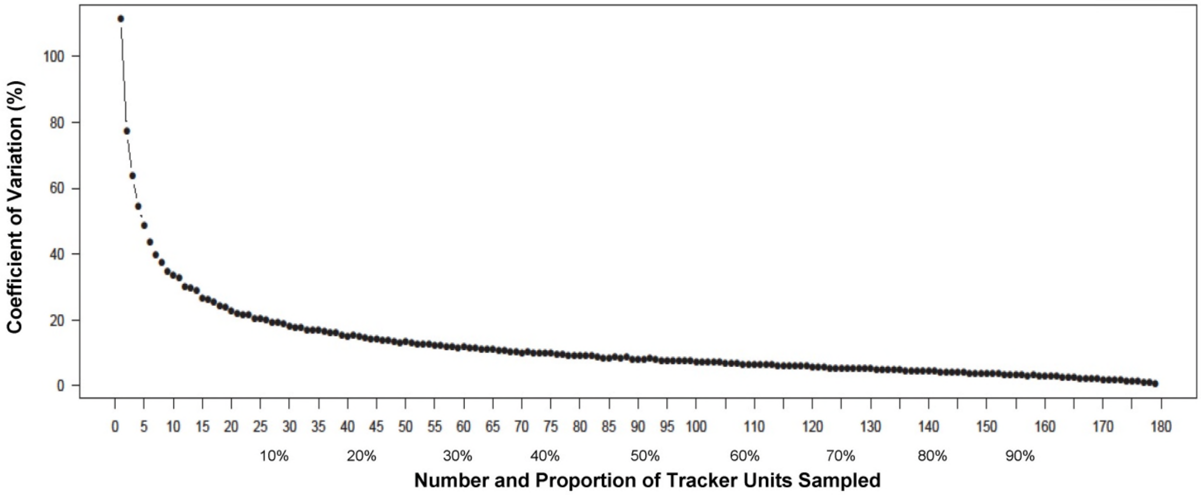

Figure 2. Resampling results from the California Valley Solar Ranch illustrating how the coefficient of variation for fatality estimates varies with proportion of area sampled.

Appendix C
Desert Sunlight Wildlife Incident Reporting System (WIRS)

DESERT SUNLIGHT
WILDLIFE INCIDENT REPORTING SYSTEM (WIRS)

BACKGROUND AND INTRODUCTION

Desert Sunlight will voluntarily implement a wildlife incident response and reporting system. Desert Sunlight will record and report all dead and injured wildlife including but not limited to birds found incidentally in the project areas over the entire life of the project as part of the project operations and monitoring efforts. The purpose of this Wildlife Incident Reporting System (WIRS) is to standardize the actions taken by site personnel in response to wildlife incidents found within project boundaries. The WIRS provides direction for site personnel who may encounter a wildlife incident in an effort to fulfill obligations in reporting wildlife incidents. Wildlife fatalities or injuries found by project personnel or others will be reported and processed following the protocols described in this document.

DESERT SUNLIGHT WIRS POLICY

This WIRS will be active for the life of the solar projects. All employees, contractors and subcontractors of Desert Sunlight have a responsibility to comply with all environmental laws and regulations. Most birds are protected by the federal MBTA, and eagles are further protected by the BGEPA. In addition, the state of California has an Endangered Species Act (CESA). Under the federal statutes, it is illegal to harm, harass, kill, or collect birds that may be found in the solar facility. A summary of these statutes is presented below. It is recognized that other wildlife including bats are generally not protected by federal or state law unless listed as a threatened or endangered species. However, it is the policy of FS to treat all wildlife incidents the same as avian incidents and include them in the WIRS.

It is illegal to collect an injured or dead bird without appropriate federal and state permits. **THE TOUCHING, POSSESSION, TRANSFER, OR TAMPERING WITH ANY WILDLIFE SPECIES (ALIVE OR DEAD) BY DESERT SUNLIGHT EMPLOYEES OR SUBCONTRACTORS IS STRICTLY PROHIBITED UNLESS CONSISTENT WITH PERMITS.** The WIRS is designed to provide a means of recording and collecting data about wildlife species found in the solar facilities to increase the understanding of solar and wildlife interactions. Desert Sunlight maintains an ongoing commitment to investigate wildlife incidents involving company facilities and to work cooperatively with federal and state agencies in an effort to minimize the potential for future bird and wildlife fatalities. The objective of this policy is to insure that the best available information about wildlife incidents found in Desert Sunlight facilities is recorded and the proper authorities are notified. It is the responsibility of Desert Sunlight employees, contractors and subcontractors to report all wildlife incidents as outlined in this WIRS.

APPLICABLE LAWS AND REGULATIONS

Migratory Bird Treaty Act

The Migratory Bird Treaty Act of 1918 (MBTA) (16 USC 703-712) is the cornerstone of migratory bird conservation and protection in the United States. The MBTA implements four treaties that provide for international protection of migratory birds. It is a strict liability statute wherein proof of intent is not an element of a "taking" violation. Wording is clear that most actions resulting in a taking or possession (permanent or temporary) of a protected species can be a violation, regardless of intent.

Specifically, the MBTA states: “Unless and except as permitted by regulations...it shall be unlawful at any time, by any means or in any manner, to pursue, hunt, take, capture, kill, attempt to take, capture or kill, possess…any migratory bird, any part, nest, or egg of any such bird…(The Act) prohibits the taking, killing possession, transportation, and importation of migratory birds, their eggs, parts, and nests, expect when specifically authorized by the Department of the Interior." The word "take" is defined as "to pursue, hunt, shoot, wound, kill, trap, capture, or collect, or attempt to pursue, hunt, shoot, wound, kill, trap capture, or collect."

The MBTA protects 836 species of migratory birds (listed in 50 CFR 10.13), including waterfowl, shorebirds, seabirds, wading birds, raptors, and passerines. Generally, the MBTA protects all birds in the U.S. except upland gamebirds (e.g., pheasant, quail, etc), rock doves (pigeons), European starlings, and English house sparrows. Nearly all birds found at Desert Sunlight are protected under the MBTA.

Bald and Golden Eagle Protection Act

In June 1940, Congress signed into law the Bald and Golden Eagle Protection Act (BGEPA) (16 USC 668-688d) which affords additional protection to the bald and golden eagle. Specifically, the BGEPA states: “Whoever, with the United States or any place subject to the jurisdiction thereof, without being permitted to do so as provided…shall knowingly or with wanton disregard for the consequences of his act take, possess, transport…at any time or in any manner, any bald or golden eagle, alive or dead, or any part, nest or egg thereof shall be fined…that the commission of each taking or other act prohibited by this section, with respect to a bald or golden eagle, shall constitute a separate violation of this section." Penalties for violations of the BGEPA are up to $250,000 and/or 2 years imprisonment for a felony (violations are defined as a felony), with fines doubled for organizations. FS

Endangered Species Act

In 1973, the Endangered Species Act (ESA) (16 USC 1513-1543) was passed to protect endangered and threatened species and to provide a means to conserve their ecosystems. Under the ESA, Federal agencies are directed to utilize their authorities to conserve listed species, as well as "Candidate" species that may be listed in the near future, and make sure that federal agencies' actions do not jeopardize the continued existence of these species. As with the MBTA and the BGEPA, the ESA as amended prohibits the taking of species listed under the act as threatened or endangered.

BLM Sensitive Species

BLM Sensitive Species are species designated by the State Director and includes only those species that are not already federal listed proposed, or candidate species, or State listed because of potential endangerment. BLM's policy is to "ensure that actions authorized, funded, or carried out do not contribute to the need to list any of these species as threatened or endangered."

California Fish and Game Code

Sections 3511, 4700, 5050, and 5515 of the California Fish and Game Code outline protection for fully protected species of mammals, birds, reptiles, amphibians, and fish. Species that are fully protected by these sections may not be taken or possessed at any time. CDFW cannot issue permits or licenses that authorize the "take" of any fully protected species, except under certain circumstances such as scientific research and live capture and relocation of such species pursuant to a permit for the protection of livestock. Furthermore, is the responsibility of the CDFW to maintain viable populations of all native species. To that end, the CDFW has designated certain vertebrate species as Species of Special Concern because declining population levels, limited ranges, and/or continuing threats have made them vulnerable to extinction**.**

DESERT SUNLIGHT WILDLIFE INCIDENT REPORTING

The following procedures are to be followed when Desert Sunlight personnel or subcontractors discover a wildlife fatality or injury while on site. These procedures are intended to be in place for the life of the project and are independent of the post-construction monitoring studies. Prior to the initiation of operations, on-site training will be provided to Desert Sunlight personnel and subcontractors regarding the implementation of this WIRS.

When To Use The WIRS - What Constitutes A Reportable Incident?

For the purposes of this reporting system, *incident* is a general term that refers to any wildlife species, or evidence thereof, that is found dead or injured within the wind project. Note that an incident may include an injured animal and does not necessarily refer only to a carcass or fatality.

An intact carcass, carcass parts, bones, scattered feathers, or an injured wildlife species all represent reportable incidents. Desert Sunlight personnel and subcontractors shall report all such discoveries even if you are uncertain if the carcass or parts are associated with the facility.

> A ***fatality*** is any find where death occurred, such as a carcass, carcass parts, bones, or feather spot (10 or more feathers).
>
> An ***injury*** or injured animal is any wildlife species with an apparent injury, or that exhibits signs of distress to the point where it cannot move under normal means or does not display normal escape or defense behavior.

Prior to assuming a wildlife species is injured, it should be observed to determine if it cannot or does not display normal behaviors. For example, raptors will occasionally walk on the ground, especially if they have captured a prey item. Raptors also "mantle" or hold their wings out and down to cover a prey item. These types of behaviors may make the wings appear broken or the animal injured. Identification of specific behaviors typical to the life cycles and distress behaviors of wildlife will be part of the Desert Sunlight wildlife training program. Always exercise caution before approaching an injured wildlife species. **<u>Under no circumstances are site personnel that are not included in the SPUT permit allowed to handle carcasses or injured animals.</u>**

Note: *Any incident involving a federally or state listed threatened or endangered species, bald eagle, or golden eagle must be reported to USFWS and/or California Department of Fish and Wildlife (CDFW) <u>within 24 hours of identification</u>. See project personnel listing for contact information.*

<u>MATERIALS NEEDED TO REPORT AN INCIDENT</u>

1. A copy of this WIRS

2. A Wildlife Incident Report Form (see Attachment 1)
3. Project Personnel Listing and Contact Information
4. Pencil, Pen
5. Camera
6. Flagging

DESERT SUNLIGHT WILDLIFE INCIDENT REPORTING PROCEDURES

The following procedures apply if the incident involves a **Wildlife Fatality** or **Injured Wildlife Species**:

- **Leave the subject animal in place**. A flag may be used to mark its location for easy finding while the data sheet is being completed. It is recommended that any flagging be marked with the date, time, and initials of the recorder. **DO NOT HANDLE THE CARCASS.**
- **Report** the find to the Site Operations Manager immediately.
- The Site Operations Manager shall complete the following steps:
    - **Photograph** the incident as it was found in the field. Take at least two pictures: a close up shot of the animal as it lays in the field and a broader view of the animal (marked by a flag) with the road, turbines, or other local features in the view. For the close up picture, place an object (e.g., radio, pencil, coin, etc.) next to the carcass for a scale of size.
    - **Prepare a Wildlife Incident Report Form.** The form and associated instructions are presented below.
    - **Report** the find to Desert Sunlight's Environmental Department.

The following procedures apply if the incident involves an **Injured Wildlife Species**:

- **Move** to a distance far enough away that it is not visibly disturbed or uneasy due to your presence. **DO NOT ATTEMPT TO CAPTURE OR HANDLE AN INJURED ANIMAL.**
- **Report** the find immediately to the Operations Site Manager
- The Site Operations Manager shall complete the following steps:
    - **Report** the find to the Environmental Affairs Lead immediately.
    - **Contact** a local rehabilitation center (*see contact list below*) for further instructions on handling and transport/pickup of the injured animal.
    - **Prepare a Wildlife Incident Report Form.** The form and instructions for filling out the form are provided below.

*** Any incident involving a federally or state listed threatened or endangered species or a bald or golden eagle must be reported to the USFWS and/or CDFW within 24 hours of identification. These**

incidents will be reported to the agency verbally by the Operations Manager or Desert Sunlight's Environmental Department.

Draft Pre-Decisional Document – Business Confidential

EXECUTIVE SUMMARY

Avian and bat monitoring surveys were conducted from August 31 to October 31, 2015 (the fall reporting period) at Desert Sunlight Solar Farm Project (Project) in accordance with the Project's Bird and Bat Conservation Strategy (BBCS). Specifically, standardized carcass searches, searcher efficiency trials, and carcass persistence trials were conducted. This report represents the third seasonal report for the first year of monitoring, and summarizes monitoring methods and results for those surveys based on the procedures and requirements specified in the BBCS. This report and the other interim quarterly reports are considered preliminary summaries of data and information. Data and final information from all four quarterly monitoring periods will be included in a comprehensive final annual report.

Included in this report are data from standardized carcass searches conducted during the fall season at the Project, defined as August 31 to October 31, 2015. For logistical reasons, fall monitoring began on Monday, August 31, 2015. Standardized carcass searches were conducted 1) in the solar field, consisting of a random stratified 29.5% sample of solar photovoltaic (PV) panels, 2) along inner portions of the fenceline, resulting in 74.4% of the length of the perimeter fence, and 3) along 47.9% of the total length of generation-tie (gen-tie) line from the Project fence to the Red Bluff Substation located south of Interstate 10 (I-10). Searches conducted within the fall season had intervals of approximately seven days.

All bird and bat fatalities and injuries that were discovered by observers, referred to as "detections" in this report, including those found incidentally and during standardized carcass searches, were documented. During the reporting period, there were 83 avian detections, and there were no detections of bats.

According to specifications of the BBCS, avian detections were categorized by likely diurnal or nocturnal migration behavior, ecological guild (e.g., raptors, songbirds, etc.), facility component, and suspected cause of death. These standardized carcass search results, along with searcher efficiency and carcass persistence rates from bias trials conducted on site, were applied to a fatality estimator model (Huso 2010) to provide a preliminary estimate of the number of fatalities that occurred at the Project during the reporting period adjusted for sources of bias. The estimate is considered preliminary because the annual report may pool information from bias trials and other data across seasons which could affect seasonal estimates.

During the reporting period, carcass persistence was influenced by carcass size and Project component. Small carcasses (0-100 g) in the arrays and along the fence (combined) had a 46% chance (90% confidence interval [CI]: 30 – 63%) of persisting through the effective search interval, medium carcasses (101 – 999 g) had a 80% (64 – 92%) chance, and large carcasses (1000+ g) had a 98% (95 – 100%) chance. Mean removal time within the arrays for small, medium, and large carcasses was 2.2, 17.4, and 203.3 days, respectively. Along the gen-tie line, chances of persistence for small, medium, and large carcasses were 8% (3 – 14%), 30% (17 – 43%), and 72% (58 – 87%), respectively; mean removal time for small, medium, and large

Comentado [FWS1]: Please include median removal times and n for each size class.

Comentado [FWS2]: Add median removal times and n for each size class.

carcasses was 0.1, 0.8, and 9.7 days, respectively. Within the solar arrays, searcher efficiency was influenced by carcass size: 55.7% for small birds, 82.1% for medium birds, and 82.9% for large birds. Along the interior of the fence, searcher efficiency ranged was 90.1% (CI: 78.1 – 100%), 94.9% (CI: 86.2 – 100%), and 98.0% (CI: 92.6 – 100%) for small, medium, and large carcasses, respectively. Along the gen-tie line, searcher efficiency ranged from 44.7% (CI: 27.4 – 62.4%), 62.5% (CI: 45.5 – 80%), and 81.0% (CI: 60.0 – 100%) for small, medium, and large carcasses, respectively.

Comentado [FWS3]: Please include n for each size class.

Composition of detections during fall 2015 included 13 avian guilds. Waterbirds and waterfowl comprised the majority of detections (n = 21), followed by rails and coots (n = 13), grassland birds and sparrows (n = 12), and warblers (n = 10). All other guilds were represented by fewer than ten detections. No bats have been detected since monitoring began at the Project. Species that migrate nocturnally were detected most frequently during fall (n = 21 species).

During fall 2015, 296 carcasses (90% CI: 198 – 461) were estimated for the solar arrays. There were an estimated 0.115 carcasses per acre (within the solar field only; 296 estimated carcasses/2,585 acres) and an estimated 0.538 carcasses per nameplate MW (296 estimated carcasses/550 MW) within the solar field.

Estimates of fatalities along the gen-tie are heavily influenced by the high rates of scavenging observed during the limited trials at the gen-tie (ie. large correction factors) and are likely very unreliable. The estimate along the gen-tie was 894 carcasses (90% CI: 362 – 2,948). No carcasses were estimated for the perimeter fenceline because there were no detections made along the fence.

1.0 INTRODUCTION

1.1 Project Background

Desert Sunlight 250, LLC and Desert Sunlight 300, LLC (collectively, Desert Sunlight) constructed and operates the Desert Sunlight Solar Farm Project (referred to in this report as "Project"), which consists of two main components: 1) a 550-megawatt (MW) photovoltaic (PV) generating facility; and 2) a 220-kilovolt (kV) generation interconnection (gen-tie) line. The Project comprises approximately 1,700 hectares (ha; 4,200 acres) of land administered by the Bureau of Land Management (BLM) six miles north of Desert Center in Riverside County, California (Figure 1).

1.2 Monitoring Plan Overview and Goals

A Bird and Bat Conservation Strategy (2014; “BBCS”) was prepared by the Project proponent in collaboration with the U.S. Fish and Wildlife Service (USFWS), California Department of Fish and Wildlife (CDFW), and BLM to guide comprehensive monitoring of impacts to birds and bats associated with operation of the Project. Final agency approval of the BBCS occurred in December 2014. Amendments to the sampling protocol along some portions of the Project fenceline were made by Desert Sunlight and approved by the BLM on February 11, 2015.

The BBCS details post-construction monitoring to be conducted and the data analysis and reporting processes that will be implemented by Desert Sunlight in collaboration with the USFWS, CDFW, and BLM. As identified in the BBCS, they are:

1. Estimate overall annual avian fatality rate and species composition associated with the Project infrastructure. This estimate will include mortality associated with solar arrays, overhead lines including the gen-tie line, perimeter fence and other features of the Project that may result in injury and fatality.
2. Determine whether there are spatial and temporal/seasonal patterns of mortality associated with project infrastructure (e.g., different fatality rates near panels on the edge of the arrays vs. the interior area of the arrays).
3. Provide information that will assist the BLM in consultation with the USFWS in understanding which species and potentially which regional populations are at risk.
4. Collect data in such a way that the BLM in consultation with the USFWS may make comparisons with other solar sites.

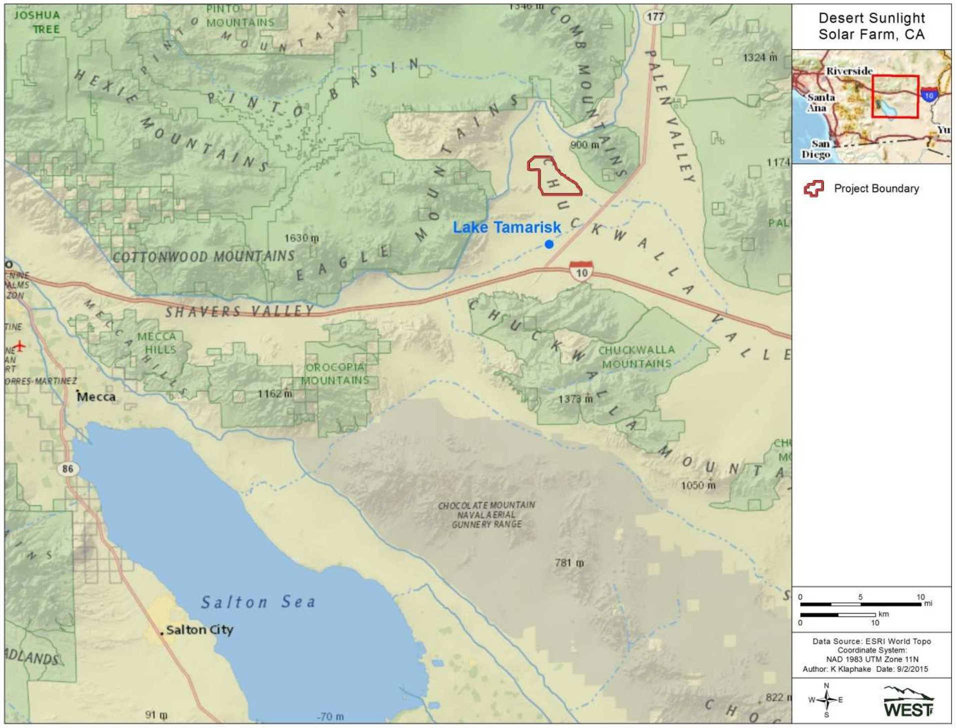

Figure 1. Desert Sunlight Solar Farm Project vicinity map, Riverside County, California.

1.3 Purpose of This Report

This report represents the third seasonal report for the first year of monitoring summarizing monitoring methods and results for avian and bat fatalities and injuries based on the procedures and requirements specified in the approved BBCS. This and the other interim quarterly reports are considered preliminary summaries of data and information. Data and final information from all four quarterly monitoring periods will be included in a comprehensive final annual report.

This report covers the period August 31 to October 31, 2015, or the 2015 fall season. For logistical reasons, fall monitoring began on Monday, August 31, 2015. All carcasses and injuries that were discovered by observers are referred to as “detections” in this report. As stated in the approved BBCS, this seasonal report includes the observed detections for likely diurnal, and likely nocturnal species, and for ecological guilds of interest (e.g., raptors, water-associated birds, passerines), for each of the facility types and suspected causes of death. Species composition of detections and the results of the bias trials are also reported. This report presents information related to the spatial distribution of detections, but no formal statistical analysis of the spatial distribution of carcasses will be conducted until the end of the monitoring year, given the limited data presently available.

2.0 METHODS

The BBCS describes the methods by which monitoring and certain analyses, including compilation of the overall fatality estimate, will occur. Below is an abridged description (see BBCS for detailed methods).

2.1 Standardized Carcass Searches

This section describes areas surveyed, the timing and frequency of searches, and the methods by which standardized searches were conducted to identify dead/injured birds and bats at the Project. Dead or injured birds and bats are called detections in this report to provide consistency in naming. This section also describes the methods for conducting carcass removal and searcher efficiency trials; how data were reported and analyzed; and the methods for producing fatality estimates for the Project.

2.1.1 *Areas Surveyed*

Standardized carcass searches were conducted at sampling units, which include the solar arrays (Table 1, 2; Figure 2); the “fenceline” defined as the perimeter fence for the Project (Table 1, Figure 2); and the gen-tie line (from the Project fence to the Red Bluff Substation on the south side of I-10; Table 1, Figure 3). Some overhead lines co-occur with solar arrays (medium voltage overhead lines [MVOH]). The MVOH were part of standardized carcass searches to the extent that they co-occured with solar arrays included in the sample (Table 2; Figure 2).

Table 1. Areas included in standardized carcass searches at the Desert Sunlight Solar Farm Project during fall (August 31 – October 31) 2015.

Project Component	Total Size	Units	% of Component Searched
Solar arrays	1045.9	Hectares	29.5[1]
Fence	16.7	Kilometers	99.0[2]
Gen-tie line	19.2	Kilometers	47.9[3]

[1] Percent area that was searched in fall 2015. Slightly less than 30% total because of unequally-sized arrays.

[2] 74.4% of the fence is fully accessible and surveyed following the standard protocol, while approximately 25% of the fence is surveyed from a distance. Fatality rates estimated for sections of the fence that are sampled were extrapolated to sections of the fence where the standard monitoring protocol cannot be used, as described in section 4.2.6 of the approved Desert Sunlight BBCS. A very short segment near the gate is not sampled due to restoration activities.

[3] 52.1% of the gen-tie will be sampled in 2016.

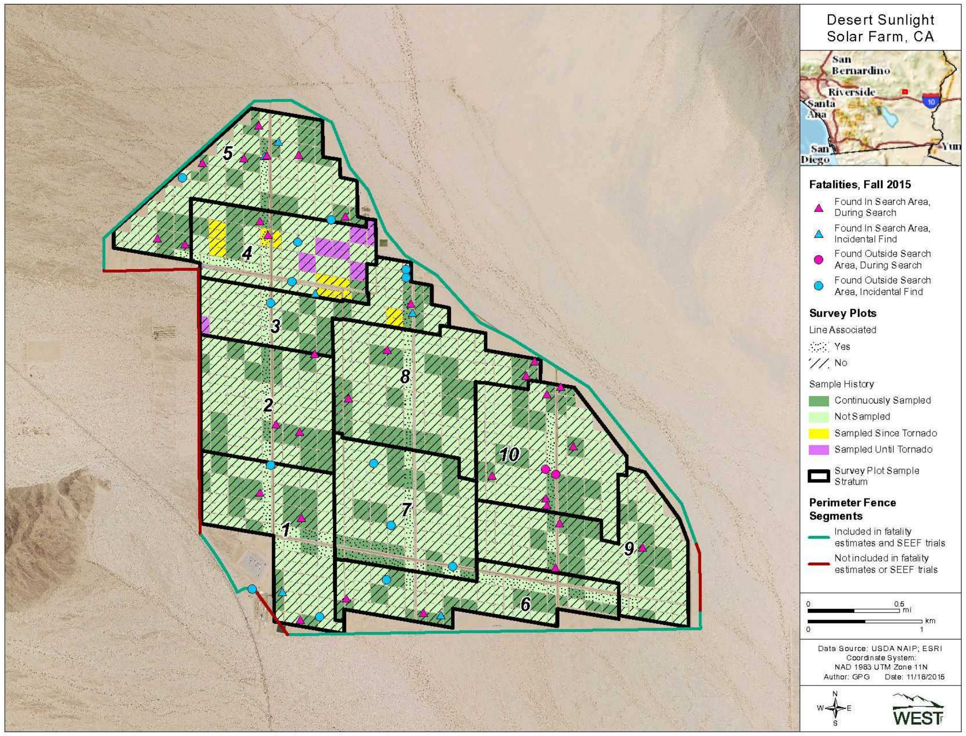

Figure 2. Areas of standardized searches and detections (those made during searches and those made incidental to operations and maintenance) at the solar field, visitor center, and overhead lines within the fence at Desert Sunlight Solar Farm Project during fall (August 31 – October 31) 2015. No detections occurred along the fence during fall 2015. The detection that appears at the fence in the map was located at the visitor center.

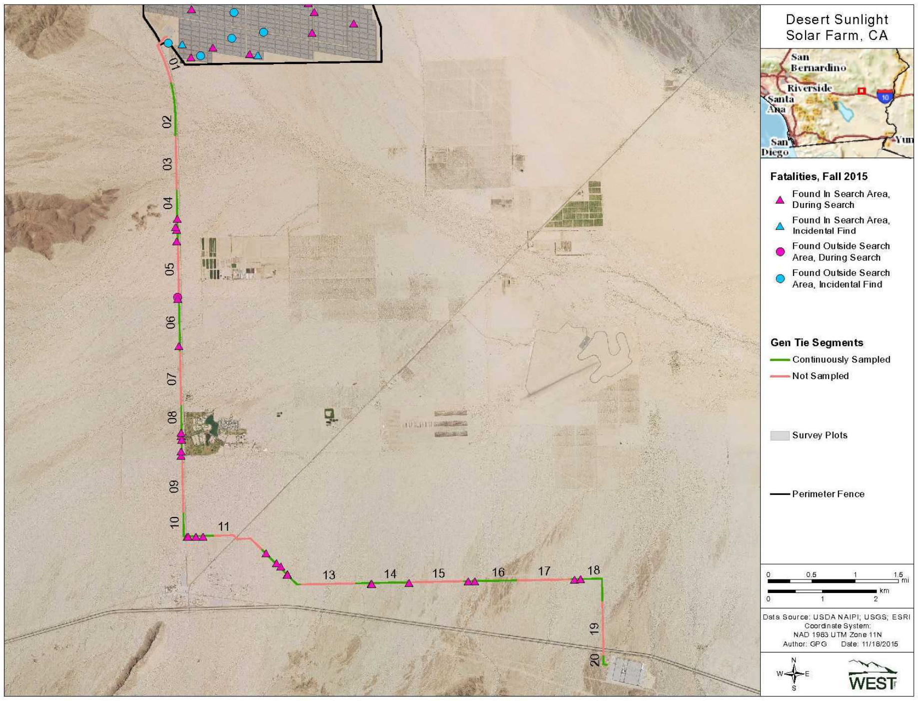

Figure 3. Areas of standardized searches and detections (those made during searches and those made incidental to operations and maintenance activities) along the generation tie line at the Desert Sunlight Solar Farm Project during fall (August 31 – October 31) 2015. Detailed maps of detections along the line are presented in Appendix A.

To ensure a balanced distribution of sample units in the solar field (defined as the collection of all photovoltaic [PV] solar panels), the entire field was divided into ten strata, and individual sampling units were randomly selected within each stratum to compose an approximately 30% sample. This sampling design ensures that units included in the sample were not spatially clumped within the solar field. The solar field consists of arrays of solar panels (referred to as a solar array) that are either 70-m or 140-m wide. The sample includes 133 of each type of array. There are 2,580 70-m rows, and 3,900 140-m rows in the sample.

2.1.1 *Search Frequency and Timing*

Standardized searches occurred during the fall survey season, which includes the period from August 31 through October 31, 2015. All project components included in standardized searches were surveyed nine times during fall. All searches took place during daylight hours from 06:30 to 17:00.

As specified in the approved Desert Sunlight BBCS, the average search interval for all Project components included in standardized carcass searches during fall was 7.0 days (median 7.0 days). Slight variation in search interval was anticipated due to weather and logistical delays.

Table 2. Area and proportion of solar arrays that are and are not associated with overhead lines at the Desert Sunlight Solar Farm Project, Riverside County, CA.

	Line-associated[1]	Not line-associated	Proportion line-associated
Entire facility	89.4 ha	956.5 ha	0.09
Standardized searches	32.2 ha	291.0 ha	0.10

[1] Line-associated area was estimated as the area of any array that fell within the 30-m strip transect below the MVOH.

2.1.2 *Search Methods*

Standardized carcass searches were performed by BLM-approved biologists, in accordance with methods outlined in the BBCS.

Within the solar field, arrays of solar panels were surveyed by observers traveling on foot. A distance sampling approach was used, whereby biologists slowly walked a transect line along the ends of rows of solar panels in a direction perpendicular to the rows, searching ahead and to the side within the array for bird and bat detections. Biologists scanned out to a maximum perpendicular distance of approximately 70 m from the transect. Biologists carried binoculars to allow them to verify the presence of a detection versus rocks or vegetation. Once a detection was confirmed, the distance of the detection to the transect line was estimated using laser range finders. Each array included in the sample was searched by observers walking two transects – one on the west side and one on the east side of the array with observers looking toward the center of the array.

Once a carcass was detected, it was photographed, and data were recorded according to specifications outlined in section 7.2.5 of the approved Desert Sunlight BBCS. Carcasses were then retrieved from their location on the ground, labeled, and placed in a freezer on site.

Most (74.4%) of the length of fenceline (approximately 10 miles; Figure 2) was searched from a vehicle using the standard protocol. Biologists searched a 6-m wide strip transect centered on the fence from the inner perimeter. Travel speed was below five miles per hour (mph) while searching. Some sections along the fence cannot be driven close to the fence line. The fence line along the western edge of the Project is drivable but the road is approximately 15 m away from the fence and the road and fence are separated by a drainage ditch. The fence along this section is covered with a tan tarp and trees and shrubs have been planted to reduce visibility of the project from the west. Additions of vegetation and the tarp likely reduce potential for bird collision with the fence. This section of the fence was driven to document carcasses, but detections along this portion of the fence are not included in adjusted fatality estimates because detection rates are likely very low. As specified in section 4.2.6 in the approved Desert Sunlight

BBCS, we assume that fatality rates are similar between the portion of fence that was searched and the portion that was not. A separate section of the fence in the southeastern corner of the Project cannot be driven because the eastern edge of the berm that bounded construction ponds is too narrow for a vehicle. Along this portion of the fence, the observer stopped at both north and south ends of the berm and used binoculars to search for carcasses. Finally, the road along a portion of the southwest fence line near the entrance gate is approximately 30 to 50 m from the road and is separated from the fence by an area that has recently undergone vegetation restoration. This area was eliminated from sampling. Fatality rates estimated for sections of the fence that were sampled were adjusted to account for the proportion of fence not sampled with the standard monitoring protocol, as specified in section 4.2.6 of the approved Desert Sunlight BBCS.

Comentado [FWS4]: Is there a reason that this can't be done using an estimator based on the fraction that was searched?

The gen-tie line was searched using a 30-m wide strip transect (i.e., 15 m of ground on either side of the overhead line). Sample units along the gen-tie line were chosen by dividing the total length of line from the Project fence south to the Red Bluff Substation just south of I-10 into 1-km segments. Thus, a 47.9% sample of the total length of the line was searched (Figure 3). Biologists slowly walked every other 1-km segment of the line, meandering the width of the strip transect, scanning for dead or injured birds or bats within 15 m (49.2 ft) of the overhead line.

For each detection, a suspected cause of death or injury was assigned based on evidence available from the detection, evidence available on Project infrastructure, and proximity of the detection to Project infrastructure. Detections that had evidence of scavenging and lacked evidence on Project infrastructure were assigned as "unknown" because it cannot be determined whether the event was caused by predation or interaction with project infrastructure. Detections that were intact (i.e., no evidence of scavenging) and located in close proximity to Project infrastructure (e.g., found directly beneath overhead lines) had a suspected cause of death attributed to the respective Project component. However, it should be noted that there is substantial uncertainty associated with cause of death assignments because no events were directly observed. Detections assigned to the "unknown" category were included in fatality estimates if they were located within standardized carcass search areas, and all detections made during the fall season are reported here.

2.2 Carcass Persistence Trials

Carcass persistence trials were conducted throughout the fall period. Carcasses from three size classes (small [0-100 g], medium [101-999], and large [1000+ g]) were used for trials. The small size class comprised house sparrows (*Passer domesticus*) and 2-3 week old coturnix quail (*Coturnix coturnix*), the medium size class comprised rock pigeons (*Columba livia*), chukar (*Alectoris chukar*), and adult coturnix quail, and the large size class comprised hen mallard (*Anas platyrhynchos*) and hen ring-necked pheasant (*Phasianus colchicus*).

2.2.1 *Carcass Persistence Data Collection*

To quantify carcass persistence rates, 15 small, 10 medium, and 5 large carcasses were randomly placed and monitored along the gen-tie line during fall 2015. Within the solar arrays the same numbers of each size category were placed, for a total of 60 carcass persistence trials at Desert Sunlight during the fall season, as specified in the approved Desert Sunlight BBCS. By placing carcasses inside (within arrays and along inner perimeter of the fence) and outside (along the gen-tie) the project fence, the possibility that there are different carcass persistence rates inside and outside the project fence is accounted for. Fifteen carcasses within the Project fence (within solar arrays and along the fence) were monitored using motion-triggered digital trail cameras, while the remaining carcasses were visited on foot, for 30 days or until the carcass had deteriorated to a condition at which it would no longer qualify as a documentable fatality. No carcasses along the gen-tie line were monitored with cameras because of theft and vandalism concerns. Carcasses without trail cameras were visited and photographed once per day for the first four days, and then every three to five days until the end of the monitoring period. To avoid training scavengers to recognize cameras as “feeding stations”, trail cameras were installed five days before specimens were placed, and two fake cameras without bias trial carcasses were also placed within the Project fence and periodically moved to new locations within the fence. Periodic ground-based checking of carcasses with trail cameras also occurred to guard against misleading indicators of carcass removal, such as wind blowing the carcass out of the camera’s field of view. To minimize potential bias caused by scavenger swamping (Smallwood 2007, Smallwood et al. 2010), carcass-persistence specimens were distributed across the entire Project, not just in areas subject to standard searches, and trials were initiated in smaller numbers on two different dates throughout the fall season.

Comentado [FWS5]: By placing carcasses in unsearched areas, doesn’t this introduce an unnecessary assumption that carcass persistence is the same in searched and unsearched areas? Have you tested that carcass persistence is the same in searched and unsearched areas?

Comentado [FWS6]: This isn’t clear. Is it possible to only distribute carcasses on two dates and have small numbers? Is it possible to distribute the carcass on more dates, so there are fewer “arriving” at any one time?

2.2.2 *Estimating Carcass Persistence Times*

Measurements of carcass persistence rates were subject to censoring. In this context, censoring refers to the instance when a value (e.g. days a carcass is present before being removed) may not be known exactly, but is known to be within a finite range. For example, suppose a carcass was checked on day 7 and was present, and was checked again on day 10, but was found to be missing. The exact time until removal is unknown; however, it is known that the carcass became unavailable at some point between 7 and 10 days. This carcass would be considered “interval censored”. Similarly, if a carcass lasts the entire 30-day trial period, that carcass is “right censored”— it is known that the carcass lasted at least 30 days, but it may have persisted longer. Because carcass persistence data were censored, persistence was analyzed using methods that can accommodate censored data and still produce unbiased estimates of the probability of persistence (Therneau 2015, Therneau and Grambsch 2000). It is beyond the scope of this document to provide statistical foundations of censored-data survival models but functions identical to those provided with the USGS-developed fatality estimator software (Huso et al 2012) were used to fit survival models to the censored carcass persistence data, and some background is available in the documentation provided with that software.

USGS-developed fatality estimator software (Huso et al 2012) was used to fit survival models to the censored carcass persistence data. The USGS software used to estimate carcass persistence calculates the period over which there is less than a 1% chance for a carcass to persist. The 'effective search interval' is defined as the shorter of a) the length of time beyond which there is less than a 1% probability that a carcass persists, and b) the actual search interval (Huso 2010). The probability of persistence is given for the effective search interval, and the probability that a carcass persists through the actual search interval is equal to *p* (persist through effective search interval) * effective search interval / actual search interval.

There were four distributions implemented in survival models used to estimate the probability a carcass is unscavenged and available to be found at the end of the search interval (*r*): exponential, Weibull, loglogistic, and lognormal. These four distributions exhibit varying degrees of flexibility in order to model a wide variety of distributions of persistence time. Akaike's Information Criterion adjusted for sample size (AICc; Akaike 1973) was used to rank the fit of each survival model with combinations of the covariates carcass size, Project component, season, and visibility, to observed carcass persistence data.

2.3 Searcher Efficiency Trials

Searcher efficiency trials were conducted throughout the fall period. Carcasses from three size classes (small, medium, and large) were used for trials. The small size class comprised house sparrows and 2-3 week old coturnix quail, the medium size class comprised rock pigeons, chukar, and older coturnix quail, and the large size class comprised hen mallards and hen ring-necked pheasants.

2.3.1 *Searcher Efficiency Data Collection*

Training of biologists on the Project-specific protocol and early assessments of habitat conditions within the solar arrays suggested that the amount of cobble present in the soil may be an important factor influencing searcher efficiency. To satisfy requirements regarding consideration of visibility class per the BBCS and address the influence of cobble cover on searcher efficiency, sample units in the solar arrays and along the gen-tie were stratified by cobble cover and assigned to one of two classes (<15% and >15% cobble cover). Classes were determined by making ocular estimates of cobble cover at each sample unit and then evaluating the frequency histogram of sample units across the range of estimated cobble cover (Figure 4). A natural break point was identified at 15% cobble cover, so the same value was chosen as the break point that defined the two cobble cover classes. Thus, in the solar arrays, two sets of searcher efficiency trials were conducted (one set in each cobble cover class; total *n* = 45 small birds, 30 medium birds, and 15 large birds as agreed upon in section 7.4 of the approved Desert Sunlight BBCS). Along the gen-tie, visibility was expected to be related to vegetation and rock cover. Thus, searcher efficiency trials along the gen-tie occurred in two visibility classes (*n* for each class = 15 small birds, 10 medium birds, and 5 large birds (easy: ≥90% bare ground, vegetation <6" tall; and more difficult: <90% bare ground, vegetation ≥6" tall). Thirty searcher efficiency trials (*n* = 15 small birds, 10 medium birds, and 5 large birds) occurred along the fence in the only visibility class present on the fence (easy visibility). During fall, a total of 180 searcher efficiency trials occurred at the Project. Locations for trials were chosen by taking a randomized sample of all locations included in standardized carcass searches.

Comentado [FWS7]: This isn't very clear. two sets of trials should be n= 30 (s); 20 (m); 10 (l). Trial carcasses of 45, 30, 15 sounds like a multiple of three. Please clarify.

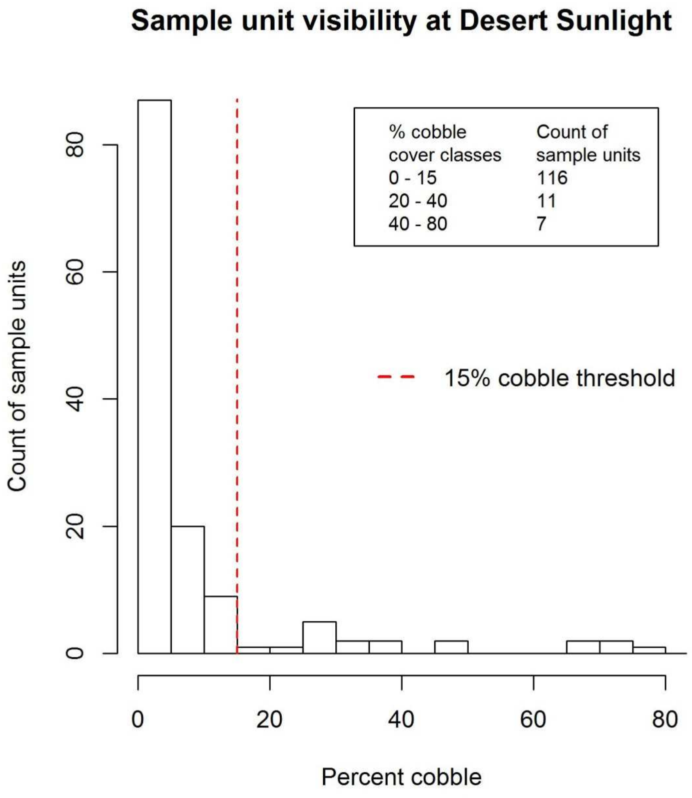

Figure 4. Frequency histogram of sample units (in the arrays only) at Desert Sunlight Solar Farm Project by estimates of cobble cover. Based on this distribution, each sample unit was assigned to one of two classes of cobble cover (<15%; >15%).

2.3.2 *Estimating Searcher Efficiency*

Searcher efficiency at Desert Sunlight was estimated separately for linear features (the project fence and the gen-tie line), and the solar arrays, reflecting the different search methods used on arrays and linear features. For linear features, logistic regression models were fit to searcher efficiency data and AICc was used to compare models. Models including effects of carcass size (three classes), visibility (two classes; gen-tie only), and season were compared to each other and the null model. Model selection indicated that the most supported model included main effects of Project component, carcass size, and season and an interaction between season and component. Once the analysis was focused on fall data only (because of the seasonal effect), the most supported model was reduced to main effects of Project component and carcass size.

Once the most supported model was chosen and appropriate classes identified, searcher efficiency, or the proportion of carcasses detected, *p*, was calculated for each class using the following equation:

$$p = \frac{Number\ of\ Carcasses\ Observed}{Number\ of\ Carcasses\ Available}$$

The data for this analysis included all searcher efficiency trial carcasses from the fall 2015 season.

For the solar arrays, searcher efficiency was evaluated using a distance sampling approach (Buckland et al. 1993). Distance sampling assumes perfect detection on the transect line (at distance = 0), an assumption that is likely valid in the solar arrays given the relatively flat & vegetation-free nature of the soil surface. A curve is fitted to the observed carcass data that predicts probability of detection as a function of distance from the transect line. The mean value of this function over a specified distance, *w,* is equal to the average searcher efficiency for a transect of width *w*. The mean value of the detection curve is the integral of the detection function calculated between 0-m and the maximum survey distance (*w;* half the width of the solar array row), divided by the maximum survey distance:

$$p = \frac{\int_0^w f(x)dx}{w},$$

where f(x) is the detection function evaluated at distance, *x*.

One departure in the methods used here, relative to the methods presented in Buckland et al. (1993), was that for this study the detection function was estimated using trial carcasses, which meant that there were both presence (detected) and absence (not detected) data available to fit the detection function (Figure 5). The availability of both presence and absence data means that the detection function can be estimated using only trial carcasses whose distribution is known. Therefore the detection function, the average searcher efficiency among the arrays, and the final fatality estimate within the arrays are all insensitive to the spatial distribution of carcasses within individual arrays, and the overall searcher efficiency estimate is valid even if the distribution of carcasses among the arrays is not uniform.

Distances of trial carcasses (trials both found and missed) from the transect line were used to fit half-normal, exponential, and hazard rate distribution detection functions for searches among the arrays, which are all commonly used functions for distance sampling surveys (Buckland et al. 1993). The fit of detection functions were compared using AICc and each model was fit with covariates (season, carcass size, cobble cover class), and without. The most supported detection function had an exponential distribution and the most supported among these models included an interactive effect of carcass size and season.

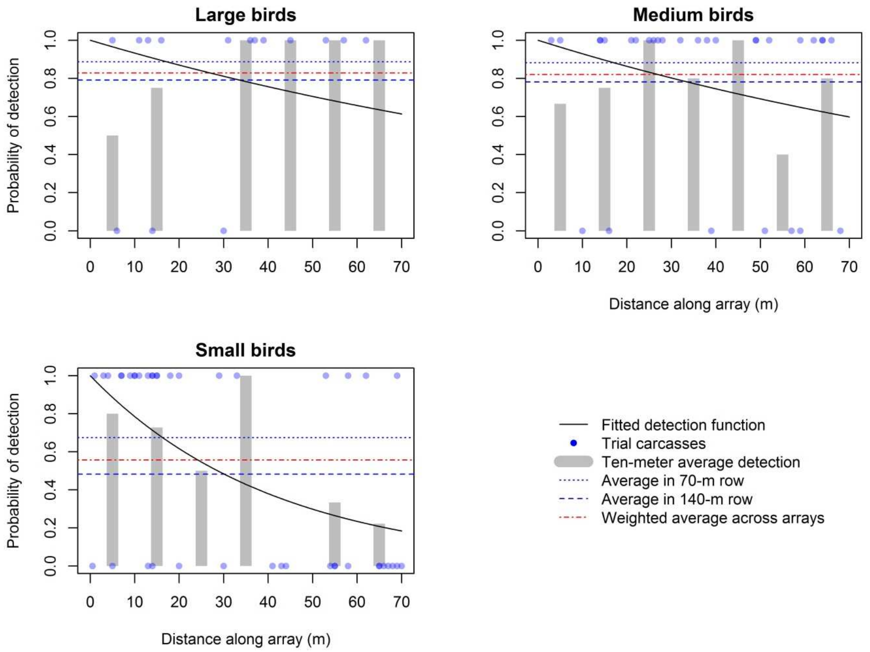

Figure 5. Estimated detection probabilities for bird carcasses by size class during fall (August 31 – October 31) 2015 at the Desert Sunlight Solar Farm Project, Riverside County, California. Distance sampling was used when searching solar arrays only. Average probability of detection over 70-m (arrays relying on a 35-m viewshed) and 140-m (arrays relying on a 70-m viewshed) panel rows in solar arrays are presented.

Comentado [FWS8]: Please include n for each figure.

Because the solar arrays were surveyed by searchers who walked down both sides of the rows of panels, the width of the search transect was specified as half the width of the rows of panels. For larger birds, there is almost certainly a non-zero detection probability beyond this distance but the bias that occurs by ignoring this non-zero detection probability is conservative (i.e. the searcher efficiency is underestimated). Some solar arrays have row widths of 70 m (search transect width of 35 m) and some have row widths of 140 m (search transect width of 70 m). The weighted average searcher efficiency is calculated based on the number of panel rows of each length in the survey sample:

$$p_{weighted\ average} = \frac{n_{70}}{n} \times \frac{\int_0^{35} f(x)dx}{35} + \frac{n_{140}}{n} \times \frac{\int_0^{70} f(x)dx}{70},$$

where n_{70} is the number of 70-m rows in the sample, n_{140} is the number of 140-m rows in the sample, and *n* is the total number of rows in the sample. Searcher efficiency was higher for the arrays with a width of 70 m, and overall searcher efficiency was estimated as a weighted average based on the proportions of 70-m arrays and 140-m arrays in the sample units.

2.4 Fatality Estimator

Fatality rate estimation is a complex task due to several variables inherent to every fatality monitoring study. Carcasses may persist for variable amounts of time due to local scavenger activity or environmental conditions leading to carcass degradation over time. Carcasses and feather spots are also detected with varying levels of success based on carcass characteristics and ground cover (e.g., vegetated areas underneath the gen-tie line versus cleared areas beneath solar panels). For these reasons, it is generally inappropriate to draw conclusions based on the raw number of fatalities alone. The desire to estimate fatalities given these variables has driven the development of several statistical methods for estimating fatalities (e.g., Smallwood 2007, Huso 2010, Korner-Nievergelt 2011). All of these fatality estimation methods share a similar underlying model. Generally, the fatality estimation for a given site may be written as:

$$F=C/rp,$$

where F is the total number of fatalities, C is the number fatalities detected and included in fatality estimation, r is the probability a carcass is unscavenged and available to be found at the end of the search interval, and p is the probability of detecting a carcass (Huso 2010). Huso (2010) describes the use of a binomial model to estimate the probability of carcass detection; in the present study, the binomial carcass detection model was used to calculate fatalities at project linear features (fence, overhead lines), and the weighted average probability of detection based on distance sampling (described above) was used to estimate probability of detection within the solar arrays.

.

All fatality estimates were calculated using the Huso estimator estimator (modified to accommodate the distance-sampling based estimate of searcher efficiency in the solar arrays), as well as 90% confidence using bootstrapping (Manly 1997). Bootstrapping is a computer simulation technique that is useful for calculating point estimates, variances, and confidence intervals for complicated test statistics. A total of 1,000 bootstrap replicates was used for each variable including of searcher efficiency (p), probability of a carcass persisting to the next search $(\hat{r})$, adjusted search interval and observed fatalities. From these bootstrap samples, the probability of available and detected was calculated and applied to the bootstrapped observed fatalities. The lower 5th and upper 95th percentiles of the 1,000 bootstrap estimates provide estimates of the lower limit and upper limit of an approximate 90% confidence interval on all estimates.

2.5 Incidental Reporting

Some detections were outside standardized search areas, or were within search areas but not observed during standardized searches. Such detections were found by WEST avian biologists and operational personnel and were considered "incidental" detections. When found by operational personnel, these detections were reported to WEST avian biologists for documentation. Data on incidental detections are reported here, as well as in the Desert

Sunlight SPUT Avian Injury and Mortality Report Forms August - October 2015. All detections made in search areas during the reporting period were included in fatality estimates, regardless of whether they were detected incidentally or during searches.

3.0 MONITORING RESULTS

3.1 Summary of Avian Detections

During fall 2015, a total of 83 avian detections (including incidentals) of 38 identified species were recorded (Table 3). The most common identified species was American coot (*Fulica americana*) with 11 detections. Most detections (n = 54, or 65.1% of total detections) occurred in the solar arrays (Figures 2 and 3; Tables 4, 5, and 6). Sixty-two (74.7%) detections occurred during standardized carcass searches and 21 (25.3%) were documented as incidentals. No bats were detected during the fall season. For fresh carcasses, body weights and weather conditions the preceding nights are described in Appendix B.

Table 3. Number of individual bird detections, by species, during fall (August 31 – October 31) 2015 at the Desert Sunlight Solar Farm Project, Riverside County, California. LA = line-associated; NLA = non-line associated.

[1] Ring-necked pheasants are used for bias trials and these two detections were likely from trial carcasses; however, ring-necked pheasants have been reported in Riverside County, CA south of the Project area near the Salton Sea (eBird 2015). Thus, we cannot be certain that these detections were exclusively from trial carcasses.

[2] See literature cited for migration behavior references; information for most species was taken from the respective species accounts found in Birds of North America (BNA) Online (http://bna.birds.cornell.edu/bna/); where information on migration behavior was lacking in BNA accounts, Newton (2008) or Murray (2004) were used.

Comentado [FWS9]: Please specify that this includes carcasses found during searches and those found incidentally. Also, please include the size category for each species.

Comentado [FWS10]: Can you mark trial carcasses so there is no confusion? You can tie a small inconspicuous but distinctive piece of string on one leg to identify trial carcasses.

Table 5. Total avian detections (including incidentals) by Project component and suspected cause of death during fall (August 31 – October 31) 2015 at the Desert Sunlight Solar Farm Project, Riverside County, California.

	Suspected Cause of Death*				
Project Component	**Collision**	**Predation**	**Other**	**Unknown**	**Percent of Total**
Fence	0	0	0	0	0.0
Visitor Center	0	0	0	1	1.2
Gen-tie line	9	1	0	18	33.7
Solar arrays					
Line-associated	2	0	0	7	10.8
Non-line associated	6	0	1	38	54.2
Percent of Total	**20.5**	**1.2**	**1.2**	**77.1**	**100.0**

* Suspected cause of death was assigned based on evidence available on the detection, evidence available on Project infrastructure, and proximity of detection to Project infrastructure. Detections that had evidence of scavenging and lacked evidence on Project infrastructure were assigned as “unknown” because it can’t be determined whether the event was caused by predation or interaction with project infrastructure. Detections that were intact (i.e., no evidence of scavenging) and located in close proximity to Project infrastructure (e.g., found directly beneath overhead lines) had a suspected cause of death attributed to the respective Project component. However, there is substantial uncertainy associated with cause of death assignments because no events were directly observed.

3.2 Temporal Patterns of Avian Detections

The number of detections recorded daily during the reporting period ranged from zero to six, and were more or less evenly distributed throughout the season (Figure 6). Daily detections peaked on September 22 and this event was reported to the agencies per Special Purpose Utilities Permit Condition H(c). The number of detections per day represents those discovered during standardized carcass searches and incidentally.

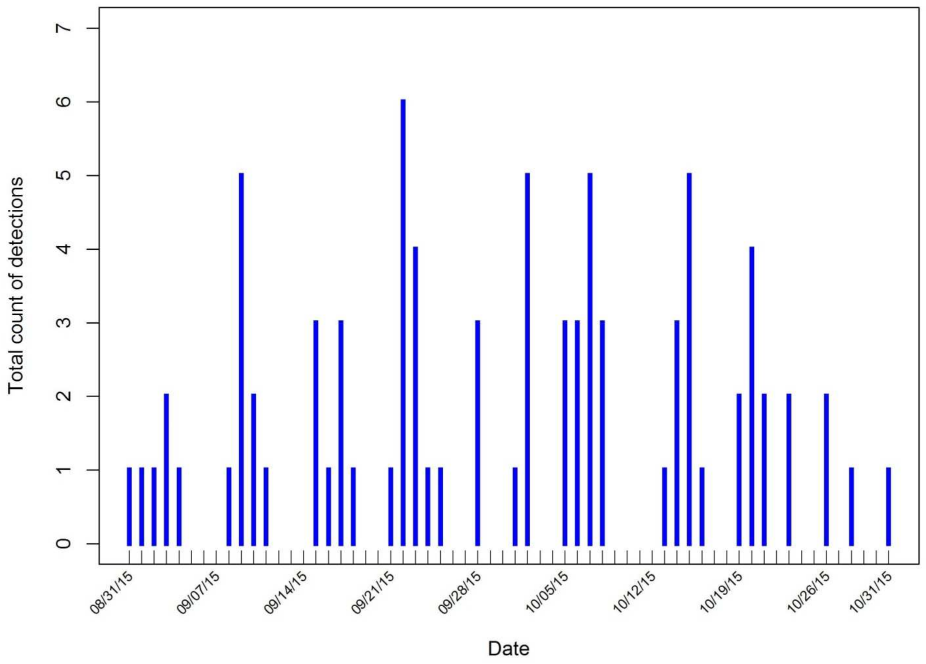

Figure 6. Total count of detections (including incidentals) by date during fall (August 31 – October 31) 2015 at the Desert Sunlight Solar Farm Project, Riverside County, California.

3.3 Spatial Distribution of Avian Detections

3.3.1 *Detections by Project Component*

During the reporting period, detections were documented from the solar arrays, the Visitor Center, and the gen-tie line; no detections occurred at the Visitor center or along the fence (Tables 3, 4, and 5). Of the 54 detections within the solar arrays, 16.7% (9) were associated either with overhead lines or arrays that co-occurred with overhead lines. Twenty-eight detections (33.7% of season total) were along the gen-tie line, and one detection (1.2% of season total) was at the Visitor Center.

3.3.2 *Feather Spot Detections*

Fourteen (16.9%) of the 83 detections made during fall consisted only of feather spots. Along the gen-tie, nine of 28 detections (32.1%) were feather spots. Five of 54 detections (9.3%) in the solar arrays were feather spots. There were no detections along the fence during fall.

3.4 Detections of Injured or Stranded Birds

There were six injured or stranded birds detected during fall 2015. Three injured birds were detected at line-associated (ruddy duck [*Oxyura jamaicensis*]) and non-line associated arrays (2; mourning dove [*Zenaida macroura*] and western grebe [*Aechmophorus occidentalis*]). Three stranded but uninjured birds were detected at line-associated (common loon [*Gavia immer*]) and non-line associated (ruddy duck and eared grebe [*Podiceps nigricollis*]) arrays. The injured mourning dove and ruddy duck were transported to wildlife rehabilitation facilities; the ruddy duck was released by the rehabilitator on the same day. The injured western grebe died before it got to a rehabilitation facility. The stranded ruddy duck, eared grebe, and common loon were evaluated for a short period for injuries and general stress and when none were observed, released at Lake Tamarisk. Three detections of injured or stranded birds were included in fall fatality estimates; three were excluded because they were found outside of a standardized carcass search area.

3.5 Summary of Bat Detections

No bats were detected during the fall 2015 season.

3.6 Carcass Persistence Trials

Data from carcass persistence trials were available from late winter, spring, summer, and fall at the solar field and gen-tie line (n = 215 total). Based on carcass persistence data from all seasons so far in 2015, survival models were compared for relative quality using the corrected AICc score, as suggested in Huso (2010). The AICc score provides a relative measure of model fit and parsimony among a selection of candidate models, and provides a framework for testing hypotheses regarding which factors contribute to carcass persistence rates. Carcass size was tested as a potentially important variable, as larger carcasses tend to persist longer and may be more likely to leave feather spots which persist for long durations, whereas smaller carcasses may be more likely to be completely removed. Project component (solar arrays, gen-tie line) was also included as a potentially important variable, as was season.

The model with lowest AICc score is typically chosen as the “most supported” model relative to other models tested; however, any model within two AICc points of the most supported model is considered competitive with the most supported model (Burnham and Anderson 2004). Preliminary modeling suggested a main effect of season, so further modeling efforts were restricted to data collected in fall only. The most supported model using only the fall data included main effects of carcass size and Project component, with a removal time that was lognormally-distributed (Appendix C). Estimates of carcass removal time and persistence probabilities from the most supported model are reported in Table 6, and estimates of proportion of carcasses remaining as a function of days since carcass placement are provided in Figure 7. Detailed estimates of carcass removal and associated confidence intervals are provided in Appendix C.

Table 6. Mean and median carcass removal time and probability of a carcass persisting through the effective search interval during the fall (August 31 – October 31) 2015 season at the Desert Sunlight Solar Farm Project, Riverside County, California.

Carcass size	Project component	Mean removal time (days)	Median removal time (days)	Probability of persistence
Small	Arrays/fence	2.2	1.5	0.46
Small	Overhead lines	0.1	0.5	0.08
Medium	Arrays/fence	17.4	16	0.80
Medium	Overhead lines	0.8	1.5	0.30
Large	Arrays/fence	203.3	30	0.98
Large	Overhead lines	9.7	3.5	0.72

Comentado [FWS11]: Also include the Time until 50% of the carcasses have been removed.

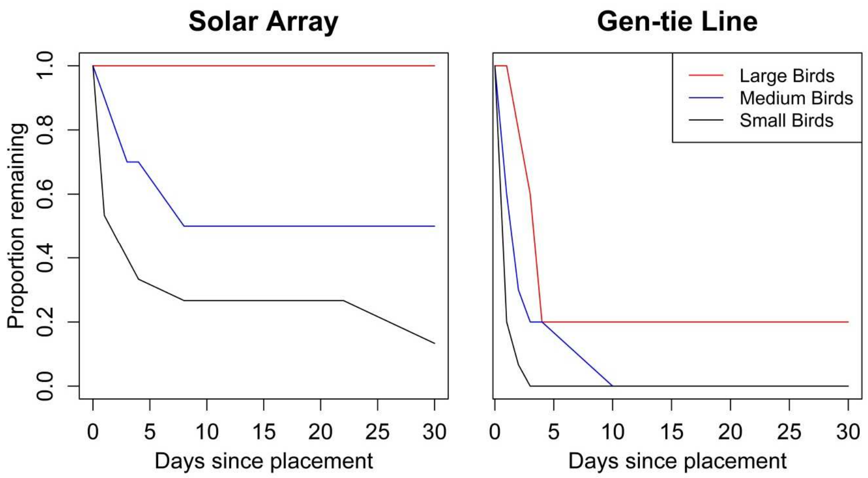

Figure 7. Proportion of trial carcasses remaining as a function of days since placement and carcass size class (n = 30, 20, and 10 for small, medium, and large size classes, respectively) during the fall (August 31 – October 31) 2015 season at the Desert Sunlight Solar Farm Project, Riverside County, California.

3.7 Searcher Efficiency Trials

During the reporting period, a total of 180 searcher efficiency trials were placed at the Project. Most trials were available to be found, but some disappeared before or during the trial. Overall, 90 trials were placed in the solar arrays and 87 were available to be found; 30 trials were placed along the perimeter fence (inner perimeter only) and 29 were available to be found; and 60 trials were placed along the gen-tie line and 51 were available to be found. Three observers conducted searches at the Project during fall. Searcher efficiency trials were conducted on each observer in approximate proportion to the number of searches they conducted at the Project, as follows: Sarah Nichols (number of trials available to be found: 28), Darin Blood (62), and Wanda Bruhns (77). All trials were included in estimation of searcher efficiency.

In the solar arrays, the model that included an effect of carcass size was chosen as the most supported model to estimate searcher efficiency (Appendix C). Within the solar arrays, searcher efficiency was: 55.7% for small birds, 82.1% for medium birds, and 82.9% for large birds (Figure 5; Appendix C).

For linear Project components, the model that included an effect of carcass size, Project component, and season was chosen as the most supported model to estimate searcher efficiency. Along the fence, searcher efficiency was 90.1% (CI: 78.1 – 100%), 94.9% (CI: 86.2 – 100%), and 98.0% (CI: 92.6 – 100%) for small, medium, and large carcasses, respectively. Along the gen-tie, searcher efficiency was 44.7% (CI: 27.4 – 62.4%), 62.5% (CI: 45.5 – 80.0%), 81.0% (CI: 60.0 – 100%) for small, medium, and large carcasses, respectively. Detailed estimates of searcher efficiency estimates specific to each component and carcass size are reported in Appendix C.

3.8 Fatality Estimates

Fatality estimates were calculated separately for each component (solar arrays, fence, and overhead lines). Ultimately, 22 detections were excluded from the fatality analysis because they were found outside standardized search areas (Table 47; Appendix C). All 83 detections ~~made~~ that occurred during fall are reported in Table 3.

Table 7. Status of detections during the fall (August 31 – October 31) 2015 season at the Desert Sunlight Solar Farm Project, Riverside County, California. All detections outside the search area were excluded from the fatality analysis, regardless of whether they occurred during a standardized carcass search or incidentally.

	Carcass search	**Incidental detection**	***Pushed to next season’s fatality estimate**	***Pulled from previous season’s fatality estimate**
Inside search area	55	6	0	0
Outside search area	7	15	0	0

* Incidental detections occurring after the last standardized carcass search in a season are considered for inclusion in the fatality analysis for the following season. This is consistent with the assumption we make throughout the monitoring seasons; that carcasses found incidentally would have been available to be found on the next scheduled search. This assumption may result in some carcasses found during one season but considered in the following season’s fatality analysis. Once a carcass has been moved to a different season’s analysis it is still subject to the same criteria for inclusion or exclusion based on location (in versus out of a searched area) and carcass age (greater than versus less than the search interval).

During fall 2015, 296 carcasses (90% CI: 198 – 461) were estimated for the solar arrays. There were an estimated 0.115 carcasses per acre (within the solar field only; 296 estimated carcasses/2,585 acres) and an estimated 0.538 carcasses per nameplate MW (296 estimated carcasses/550 MW) within the solar field.

Estimates of fatalities along the gen-tie are heavily influenced by the high rates of scavenging observed during the limited trials at the gen-tie (i.e., large correction factors) and are likely very unreliable. The estimate along the gen-tie was 894 carcasses (90% CI: 362 – 2,948). No carcasses were estimated for the perimeter fenceline because there were no detections made along the fence. A complete list of estimates for each Project component and carcass size class with confidence intervals is presented in Appendix C.

4.0 DISCUSSION

The 2015 fall season represented the third full season of standardized monitoring at Desert Sunlight per the BBCS. Searcher efficiency and carcass persistence trials were conducted concurrently at the solar arrays, fencelines, and along the gen-tie line. Data from these trials were used to produce fatality estimates adjusted for searcher efficiency and carcass persistence bias. Although these estimates were produced from a statistically robust sample, only limited inference may be drawn from three seasons of data. These results should be considered preliminary because estimating carcass persistence, searcher efficiency, and adjusted numbers of fatalities within each season represents information based on a limited sample size. As more data are collected throughout the monitoring year (and additional quality assurance/quality control measures occur, for example characterizing feather spots to species or size class), data from all seasons may be pooled. At that time, data will be tested for seasonal differences retrospectively, but because seasonal estimates will be produced from the much larger annual data set, they may differ from what is reported here because they are based on a larger, more informative sample.

4.1 Carcass Persistence and Searcher Efficiency Trials

The degree to which carcasses persist on the landscape depends on a variety of factors reflecting seasonal and inter-annual variation in habitat, climate, and the scavenger community. The composition and activity patterns of the scavenger community often vary seasonally as birds migrate, new juvenile birds and mammals join the local population, and mammalian scavengers variably hibernate or estivate. The scavenger community may also vary substantially from year to year because of variation in annual reproduction and survival related to changes in landscape condition. Climatic conditions that vary seasonally and annually also may contribute to variation in carcass decay and removal rates due to variation in temperatures, solar insolation, wind patterns, and the frequency of flooding events. Thus, rates of carcass persistence reported here should be interpreted cautiously as they may change over the coming months.

Fatality estimates are influenced by the relationship between carcass removal dynamics and search intervals. In practical terms, longer search intervals reduce average probability that a carcass persists until the next search. In terms of the analysis, this can manifest as a lower probability of persistence through the effective search interval, or an effective search interval that is shorter than the nominal search interval. In either case, the adjustment to carcass counts due to carcass removal dynamics is calculated as

$$\frac{length\ of\ effective\ search\ interval}{length\ of\ nominal\ search\ interval * average\ probability\ of\ persistence\ through\ the\ effective\ search\ interval}$$

The adjustment to estimated fatality for carcass removal increases with longer search intervals, and the variance in the estimate may increase, also.

Carcass persistence at the Project is clearly influenced by whether a carcass is located in the solar field (inside the perimeter fence) or along the gen-tie (outside the perimeter fence), with higher removal rates occurring along the gen-tie. Although the same scavenger species may occur at both Project components, a difference in scavenger density or activity between the components could possibly be responsible for the different rates of carcass persistence. If there are differences in scavenging rates between the trial carcasses and naturally-occurring carcasses, it is possible that the high scavenging rates observed along the gen-tie have resulted in inflated fatality estimates. This hypothesis may be evaluated in the annual report by comparing persistence rates of trial carcasses to the age of carcasses detected by observers. Given the very high scavenging rates along the gen-tie line, fatality estimates for the gen-tie are unreliable.

Searcher efficiency was influenced by Project component, carcass size, and season. In the solar arrays, searcher efficiency was high (>0.5) for all carcass size classes and this is likely influenced by the limited vegetation cover beneath solar panels. Beneath the gen-tie line, vegetation cover is higher in some portions of the strip transects, but results reported here support the hypothesis that visibility class was not a factor in searcher efficiency along the gen-tie line during fall. Placement of trial carcasses in both difficult and easy visibility classes ensures that the adjustment due to searcher efficiency accounts for both visibility classes, even if there is a real difference in searcher efficiency that cannot be detected with the trial data.

4.2 Distribution of Fatalities and Fatality Estimates

Detections were distributed throughout the fall season, and there were no clear peaks in detections associated with a particular date or range of dates. Tapering of daily detections at the beginning and end of the fall season (Figure 6) suggests that the current dates that define the season likely capture the majority of fall migration at the Project.

Most (65.1%) of the 83 detections made during fall were in the solar field. Approximately 13% of the carcasses found in search plots had overhead lines associated with those plots and 10% of the plots searched had lines associated with them, suggesting overhead lines within the solar field may not influence mortality. The absence of any detections along the fence in fall coupled with the very low number of detections in previous seasons (spring: 2; summer: 1) and relatively high carcass persistence rates inside the fence suggest the perimeter fence at the Project may not be an important source of mortality.

Composition of detections during fall 2015 included 13 avian guilds. Waterbirds and waterfowl comprised the majority of detections (n = 21), followed by rails and coots (n = 13), grassland birds and sparrows (n = 12), and warblers (n = 10). All other guilds were represented by fewer than ten detections. No bats have been detected since monitoring began at the Project. Species that migrate nocturnally were detected most frequently during fall (n = 21 species). Ring-necked pheasants were included in the list of detected birds (Table 3), but these detections were most likely from trial carcasses. However, because ring-necked pheasant have been reported in

Riverside County, CA (eBird 2015) south of the Project area near the Salton Sea, we could not be certain that both detections were from trial carcasses.

Detections attributed to an unknown cause accounted for 77.1% of all detections during the reporting period, and most of those attributed to an unknown cause were found in the solar arrays. Of the 54 detections made in the solar arrays, 11.1% were feather spots. Determining a cause of mortality from a feather spot is challenging because there is rarely visible evidence available on which to determine a cause of death. Thus, feather spots with an unknown cause of mortality could be encountered anywhere birds occur, and an unknown cause of a sizeable proportion of the carcasses is not unique to the Project. Further, the relatively large proportion of feather spots (18.1%) among the detections for the Project as a whole may inflate the fatality estimate based on the potential for multiple feather spots resulting from one fatality, feather spots resulting from predation not associated with the facility, or other causes.

Draft Pre-Decisional Document – Business Confidential

EXECUTIVE SUMMARY

Avian and bat monitoring surveys were conducted from August 31 to October 31, 2015 (the fall reporting period) at Desert Sunlight Solar Farm Project (Project) in accordance with the Project's Bird and Bat Conservation Strategy (BBCS). Specifically, standardized carcass searches, searcher efficiency trials, and carcass persistence trials were conducted. This report represents the third seasonal report for the first year of monitoring, and summarizes monitoring methods and results for those surveys based on the procedures and requirements specified in the BBCS. This report and the other interim quarterly reports are considered preliminary summaries of data and information. Data and final information from all four quarterly monitoring periods will be included in a comprehensive final annual report.

Included in this report are data from standardized carcass searches conducted during the fall season at the Project, defined as August 31 to October 31, 2015. For logistical reasons, fall monitoring began on Monday, August 31, 2015. Standardized carcass searches were conducted 1) in the solar field, consisting of a random stratified 29.5% sample of solar photovoltaic (PV) panels, 2) along inner portions of the fenceline, resulting in 74.4% of the length of the perimeter fence, and 3) along 47.9% of the total length of generation-tie (gen-tie) line from the Project fence to the Red Bluff Substation located south of Interstate 10 (I-10). Searches conducted within the fall season had intervals of approximately seven days.

All bird and bat fatalities and injuries that were discovered by observers, referred to as "detections" in this report, including those found incidentally and during standardized carcass searches, were documented. During the reporting period, there were 83 avian detections, and there were no detections of bats.

According to specifications of the BBCS, avian detections were categorized by likely diurnal or nocturnal migration behavior, ecological guild (e.g., raptors, songbirds, etc.), facility component, and suspected cause of death. These standardized carcass search results, along with searcher efficiency and carcass persistence rates from bias trials conducted on site, were applied to a fatality estimator model (Huso 2010) to provide a preliminary estimate of the number of fatalities that occurred at the Project during the reporting period adjusted for sources of bias. The estimate is considered preliminary because the annual report may pool information from bias trials and other data across seasons which could affect seasonal estimates.

During the reporting period, carcass persistence was influenced by carcass size and Project component. Small carcasses (0-100 g) in the arrays and along the fence (combined) had a 46% chance (90% confidence interval [CI]: 30 – 63%) of persisting through the effective search interval, medium carcasses (101 – 999 g) had a 80% (64 – 92%) chance, and large carcasses (1000+ g) had a 98% (95 – 100%) chance. Mean removal time within the arrays for small, medium, and large carcasses was 2.2, 17.4, and 203.3 days, respectively. Along the gen-tie line, chances of persistence for small, medium, and large carcasses were 8% (3 – 14%), 30% (17 – 43%), and 72% (58 – 87%), respectively; mean removal time for small, medium, and large

carcasses was 0.1, 0.8, and 9.7 days, respectively. Within the solar arrays, searcher efficiency was influenced by carcass size: 55.7% for small birds, 82.1% for medium birds, and 82.9% for large birds. Along the fence, searcher efficiency ranged was 90.1% (CI: 78.1 – 100%), 94.9% (CI: 86.2 – 100%), and 98.0% (CI: 92.6 – 100%) for small, medium, and large carcasses, respectively. Along the gen-tie line, searcher efficiency ranged from 44.7% (CI: 27.4 – 62.4%), 62.5% (CI: 45.5 – 80%), and 81.0% (CI: 60.0 – 100%) for small, medium, and large carcasses, respectively.

Composition of detections during fall 2015 included 13 avian guilds. Waterbirds and waterfowl comprised the majority of detections (n = 21), followed by rails and coots (n = 13), grassland birds and sparrows (n = 12), and warblers (n = 10). All other guilds were represented by fewer than ten detections. No bats have been detected since monitoring began at the Project. Species that migrate nocturnally were detected most frequently during fall (n = 21 species).

During fall 2015, 296 carcasses (90% CI: 198 – 461) were estimated for the solar arrays. There were an estimated 0.115 carcasses per acre (within the solar field only; 296 estimated carcasses/2,585 acres) and an estimated 0.538 carcasses per nameplate MW (296 estimated carcasses/550 MW) within the solar field.

Estimates of fatalities along the gen-tie are heavily influenced by the high rates of scavenging observed during the limited trials at the gen-tie (ie. large correction factors) and are likely very unreliable. The estimate along the gen-tie was 894 carcasses (90% CI: 362 – 2,948). No carcasses were estimated for the perimeter fenceline because there were no detections made along the fence.

1.0 INTRODUCTION

1.1 Project Background

Desert Sunlight 250, LLC and Desert Sunlight 300, LLC (collectively, Desert Sunlight) constructed and operates the Desert Sunlight Solar Farm Project (referred to in this report as "Project"), which consists of two main components: 1) a 550-megawatt (MW) photovoltaic (PV) generating facility; and 2) a 220-kilovolt (kV) generation interconnection (gen-tie) line. The Project comprises approximately 1,700 hectares (ha; 4,200 acres) of land administered by the Bureau of Land Management (BLM) six miles north of Desert Center in Riverside County, California (Figure 1).

1.2 Monitoring Plan Overview and Goals

A Bird and Bat Conservation Strategy (2014; “BBCS”) was prepared by the Project proponent in collaboration with the U.S. Fish and Wildlife Service (USFWS), California Department of Fish and Wildlife (CDFW), and BLM to guide comprehensive monitoring of impacts to birds and bats associated with operation of the Project. Final agency approval of the BBCS occurred in December 2014. Amendments to the sampling protocol along some portions of the Project fenceline were made by Desert Sunlight and approved by the BLM on February 11, 2015.

The BBCS details post-construction monitoring to be conducted and the data analysis and reporting processes that will be implemented by Desert Sunlight in collaboration with the USFWS, CDFW, and BLM. As identified in the BBCS, they are:

1. Estimate overall annual avian fatality rate and species composition associated with the Project infrastructure. This estimate will include mortality associated with solar arrays, overhead lines including the gen-tie line, perimeter fence and other features of the Project that may result in injury and fatality.
2. Determine whether there are spatial and temporal/seasonal patterns of mortality associated with project infrastructure (e.g., different fatality rates near panels on the edge of the arrays vs. the interior area of the arrays).
3. Provide information that will assist the BLM in consultation with the USFWS in understanding which species and potentially which regional populations are at risk.
4. Collect data in such a way that the BLM in consultation with the USFWS may make comparisons with other solar sites.

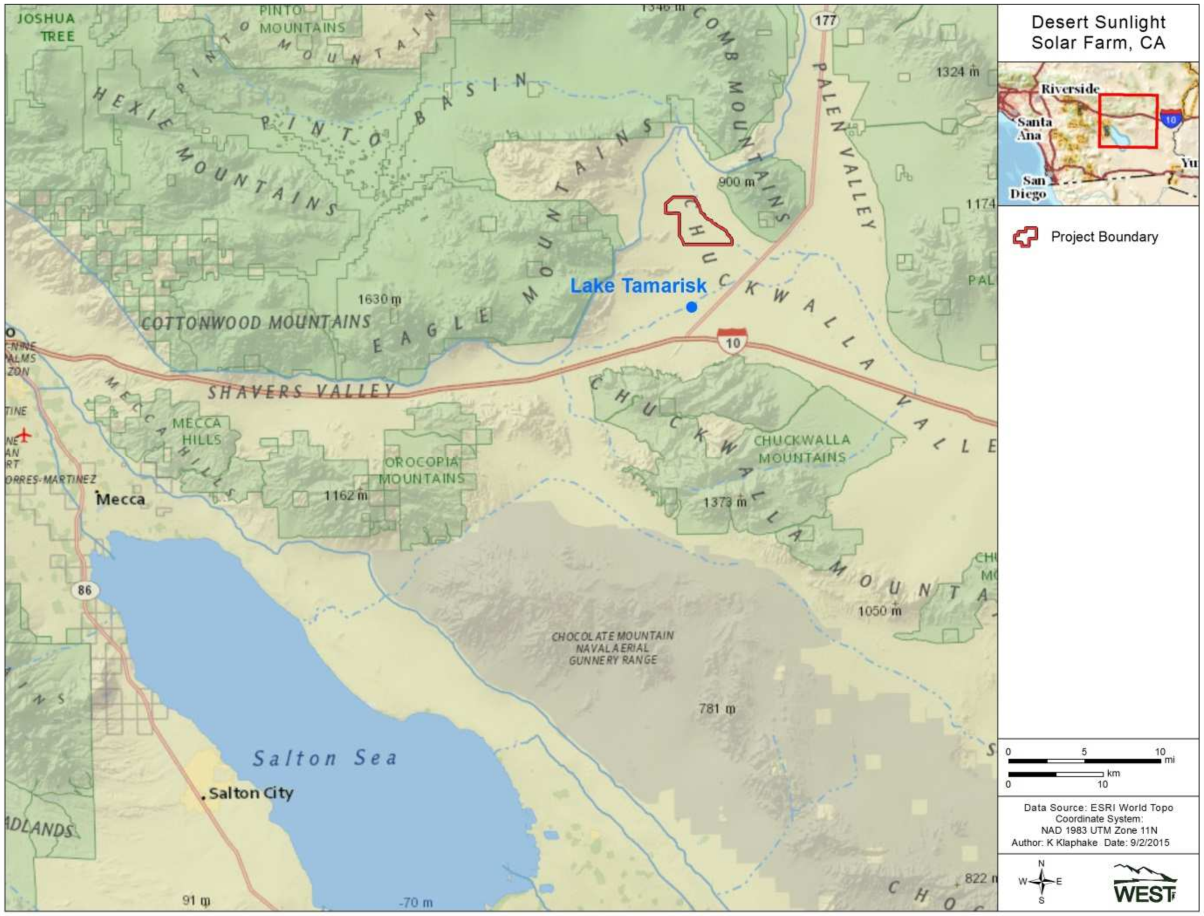

Figure 1. Desert Sunlight Solar Farm Project vicinity map, Riverside County, California.

1.3 Purpose of This Report

This report represents the third seasonal report for the first year of monitoring summarizing monitoring methods and results for avian and bat fatalities and injuries based on the procedures and requirements specified in the approved BBCS. This and the other interim quarterly reports are considered preliminary summaries of data and information. Data and final information from all four quarterly monitoring periods will be included in a comprehensive final annual report.

This report covers the period August 31 to October 31, 2015, or the 2015 fall season. For logistical reasons, fall monitoring began on Monday, August 31, 2015. All carcasses and injuries that were discovered by observers are referred to as “detections” in this report. As stated in the approved BBCS, this seasonal report includes the observed detections for likely diurnal, and likely nocturnal species, and for ecological guilds of interest (e.g., raptors, water-associated birds, passerines), for each of the facility types and suspected causes of death. Species composition of detections and the results of the bias trials are also reported. This report presents information related to the spatial distribution of detections, but no formal statistical analysis of the spatial distribution of carcasses will be conducted until the end of the monitoring year, given the limited data presently available.

2.0 METHODS

The BBCS describes the methods by which monitoring and certain analyses, including compilation of the overall fatality estimate, will occur. Below is an abridged description (see BBCS for detailed methods).

2.1 Standardized Carcass Searches

This section describes areas surveyed, the timing and frequency of searches, and the methods by which standardized searches were conducted to identify dead/injured birds and bats at the Project. Dead or injured birds and bats are called detections in this report to provide consistency in naming. This section also describes the methods for conducting carcass removal and searcher efficiency trials; how data were reported and analyzed; and the methods for producing fatality estimates for the Project.

2.1.1 *Areas Surveyed*

Standardized carcass searches were conducted at sampling units, which include the solar arrays (Table 1, 2; Figure 2); the "fenceline" defined as the perimeter fence for the Project (Table 1, Figure 2); and the gen-tie line (from the Project fence to the Red Bluff Substation on the south side of I-10; Table 1, Figure 3). Some overhead lines co-occur with solar arrays (medium voltage overhead lines [MVOH]). The MVOH were part of standardized carcass searches to the extent that they co-occured with solar arrays included in the sample (Table 2; Figure 2).

Table 1. Areas included in standardized carcass searches at the Desert Sunlight Solar Farm Project during fall (August 31 – October 31) 2015.

Project Component	Total Size	Units	% of Component Searched
Solar arrays	1045.9	Hectares	29.5[1]
Fence	16.7	Kilometers	99.0[2]
Gen-tie line	19.2	Kilometers	47.9[3]

[1] Percent area that was searched in fall 2015. Slightly less than 30% total because of unequally-sized arrays.

[2] 74.4% of the fence is fully accessible and surveyed following the standard protocol, while approximately 25% of the fence is surveyed from a distance. Fatality rates estimated for sections of the fence that are sampled were extrapolated to sections of the fence where the standard monitoring protocol cannot be used, as described in section 4.2.6 of the approved Desert Sunlight BBCS. A very short segment near the gate is not sampled due to restoration activities.

[3] 52.1% of the gen-tie will be sampled in 2016.

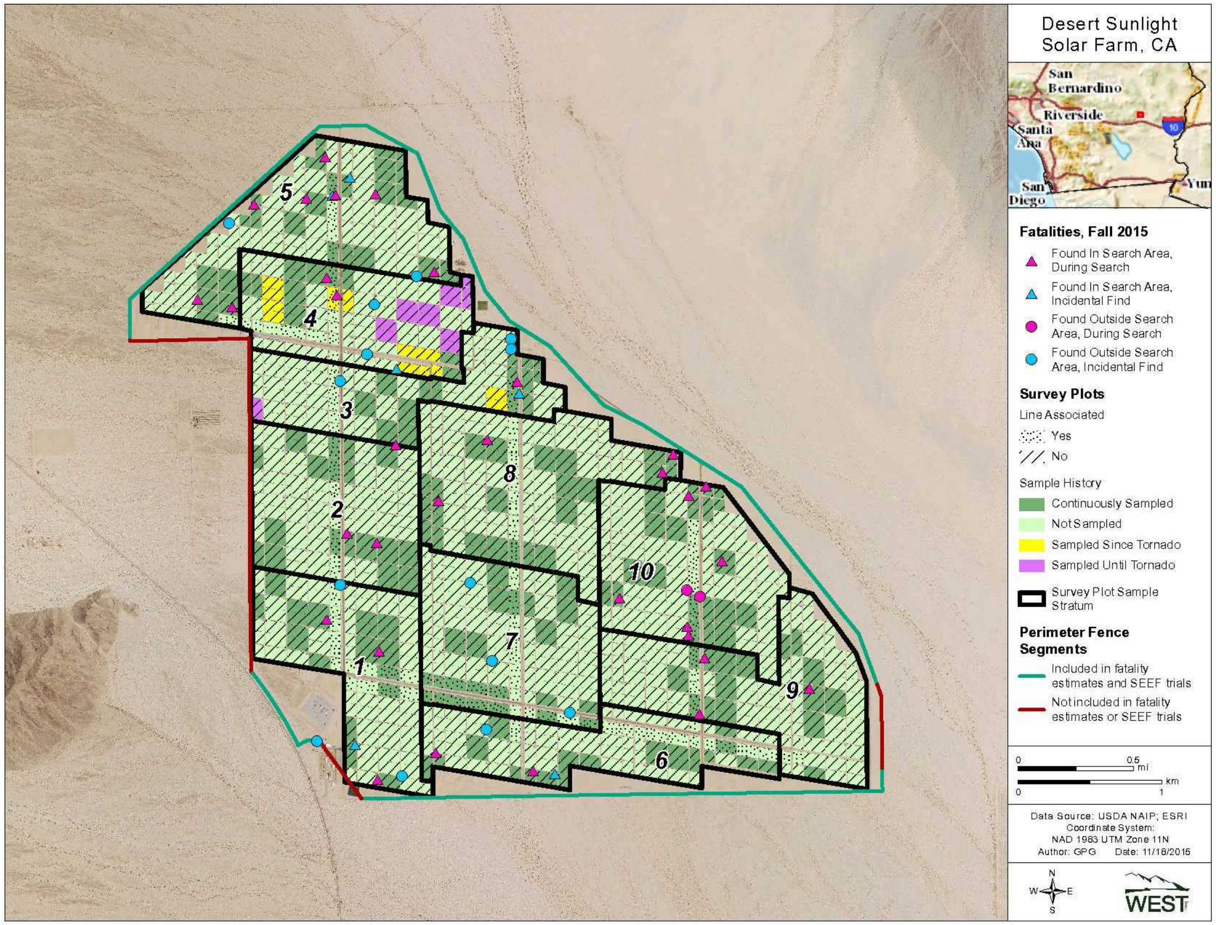

Figure 2. Areas of standardized searches and detections (those made during searches and those made incidental to operations and maintenance) at the solar field, visitor center, and overhead lines within the fence at Desert Sunlight Solar Farm Project during fall (August 31 – October 31) 2015. No detections occurred along the fence during fall 2015. The detection that appears at the fence in the map was located at the visitor center.

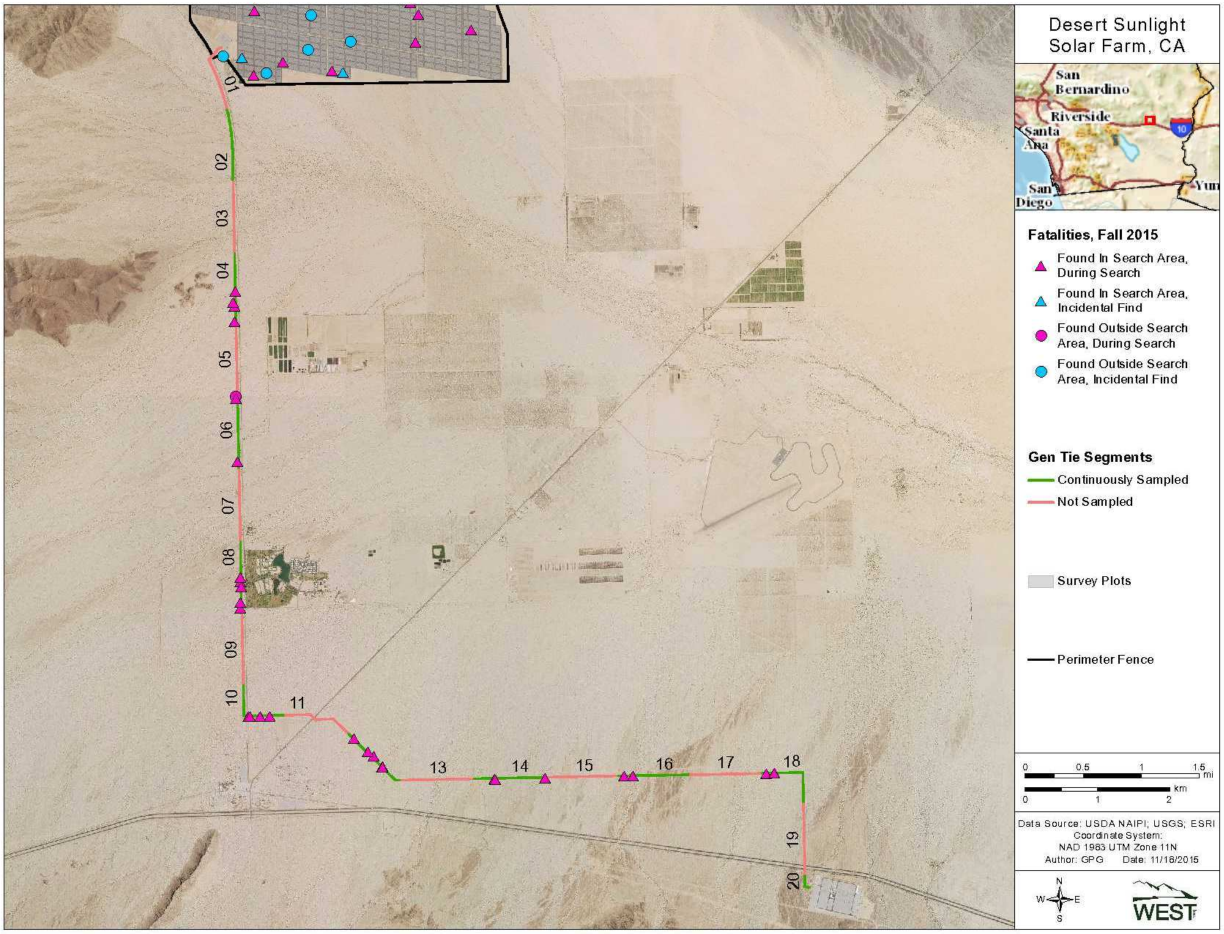

Figure 3. Areas of standardized searches and detections (those made during searches and those made incidental to operations and maintenance activities) along the generation tie line at the Desert Sunlight Solar Farm Project during fall (August 31 – October 31) 2015. Detailed maps of detections along the line are presented in Appendix A.

To ensure a balanced distribution of sample units in the solar field (defined as the collection of all photovoltaic [PV] solar panels), the entire field was divided into ten strata, and individual sampling units were randomly selected within each stratum to compose an approximately 30% sample. This sampling design ensures that units included in the sample were not spatially clumped within the solar field. The solar field consists of arrays of solar panels (referred to as a solar array) that are either 70-m or 140-m wide. The sample includes 133 of each type of array. There are 2,580 70-m rows, and 3,900 140-m rows in the sample.

2.1.1 *Search Frequency and Timing*

Standardized searches occurred during the fall survey season, which includes the period from August 31 through October 31, 2015. All project components included in standardized searches were surveyed nine times during fall. All searches took place during daylight hours from 06:30 to 17:00.

As specified in the approved Desert Sunlight BBCS, the average search interval for all Project components included in standardized carcass searches during fall was 7.0 days (median 7.0 days). Slight variation in search interval was anticipated due to weather and logistical delays.

Table 2. Area and proportion of solar arrays that are and are not associated with overhead lines at the Desert Sunlight Solar Farm Project, Riverside County, CA.

	Line-associated[1]	Not line-associated	Proportion line-associated
Entire facility	89.4 ha	956.5 ha	0.09
Standardized searches	32.2 ha	291.0 ha	0.10

[1] Line-associated area was estimated as the area of any array that fell within the 30-m strip transect below the MVOH.

2.1.2 *Search Methods*

Standardized carcass searches were performed by BLM-approved biologists, in accordance with methods outlined in the BBCS.

Within the solar field, arrays of solar panels were surveyed by observers traveling on foot. A distance sampling approach was used, whereby biologists slowly walked a transect line along the ends of rows of solar panels in a direction perpendicular to the rows, searching ahead and to the side within the array for bird and bat detections. Biologists scanned out to a maximum perpendicular distance of approximately 70 m from the transect. Biologists carried binoculars to allow them to verify the presence of a detection versus rocks or vegetation. Once a detection was confirmed, the distance of the detection to the transect line was estimated using laser range finders. Each array included in the sample was searched by observers walking two transects – one on the west side and one on the east side of the array with observers looking toward the center of the array.

Once a carcass was detected, it was photographed, and data were recorded according to specifications outlined in section 7.2.5 of the approved Desert Sunlight BBCS. Carcasses were then retrieved from their location on the ground, labeled, and placed in a freezer on site.

Most (74.4%) of the length of fenceline (approximately 10 miles; Figure 2) was searched from a vehicle using the standard protocol. Biologists searched a 6-m wide strip transect centered on the fence from the inner perimeter. Travel speed was below five miles per hour (mph) while searching. Some sections along the fence cannot be driven close to the fence line. The fence line along the western edge of the Project is drivable but the road is approximately 15 m away from the fence and the road and fence are separated by a drainage ditch. The fence along this section is covered with a tan tarp and trees and shrubs have been planted to reduce visibility of the project from the west. Additions of vegetation and the tarp likely reduce potential for bird collision with the fence. This section of the fence was driven to document carcasses, but detections along this portion of the fence are not included in adjusted fatality estimates because detection rates are likely very low. As specified in section 4.2.6 in the approved Desert Sunlight

BBCS, we assume that fatality rates are similar between the portion of fence that was searched and the portion that was not. A separate section of the fence in the southeastern corner of the Project cannot be driven because the eastern edge of the berm that bounded construction ponds is too narrow for a vehicle. Along this portion of the fence, the observer stopped at both north and south ends of the berm and used binoculars to search for carcasses. Finally, the road along a portion of the southwest fence line near the entrance gate is approximately 30 to 50 m from the road and is separated from the fence by an area that has recently undergone vegetation restoration. This area was eliminated from sampling. Fatality rates estimated for sections of the fence that were sampled were adjusted to account for the proportion of fence not sampled with the standard monitoring protocol, as specified in section 4.2.6 of the approved Desert Sunlight BBCS.

The gen-tie line was searched using a 30-m wide strip transect (i.e., 15 m of ground on either side of the overhead line). Sample units along the gen-tie line were chosen by dividing the total length of line from the Project fence south to the Red Bluff Substation just south of I-10 into 1-km segments. Thus, a 47.9% sample of the total length of the line was searched (Figure 3). Biologists slowly walked every other 1-km segment of the line, meandering the width of the strip transect, scanning for dead or injured birds or bats within 15 m (49.2 ft) of the overhead line.

For each detection, a suspected cause of death or injury was assigned based on evidence available from the detection, evidence available on Project infrastructure, and proximity of the detection to Project infrastructure. Detections that had evidence of scavenging and lacked evidence on Project infrastructure were assigned as “unknown” because it cannot be determined whether the event was caused by predation or interaction with project infrastructure. Detections that were intact (i.e., no evidence of scavenging) and located in close proximity to Project infrastructure (e.g., found directly beneath overhead lines) had a suspected cause of death attributed to the respective Project component. However, it should be noted that there is substantial uncertainty associated with cause of death assignments because no events were directly observed. Detections assigned to the “unknown” category were included in fatality estimates if they were located within standardized carcass search areas, and all detections made during the fall season are reported here.

2.2 Carcass Persistence Trials

Carcass persistence trials were conducted throughout the fall period. Carcasses from three size classes (small [0-100 g], medium [101-999], and large [1000+ g]) were used for trials. The small size class comprised house sparrows (*Passer domesticus*) and 2-3 week old coturnix quail (*Coturnix coturnix*), the medium size class comprised rock pigeons (*Columba livia*), chukar (*Alectoris chukar*), and adult coturnix quail, and the large size class comprised hen mallard (*Anas platyrhynchos*) and hen ring-necked pheasant (*Phasianus colchicus*).

2.2.1 *Carcass Persistence Data Collection*

To quantify carcass persistence rates, 15 small, 10 medium, and 5 large carcasses were randomly placed and monitored along the gen-tie line during fall 2015. Within the solar arrays the same numbers of each size category were placed, for a total of 60 carcass persistence trials at Desert Sunlight during the fall season, as specified in the approved Desert Sunlight BBCS. By placing carcasses inside (within arrays and along inner perimeter of the fence) and outside (along the gen-tie) the project fence, the possibility that there are different carcass persistence rates inside and outside the project fence is accounted for. Fifteen carcasses within the Project fence (within solar arrays and along the fence) were monitored using motion-triggered digital trail cameras, while the remaining carcasses were visited on foot, for 30 days or until the carcass had deteriorated to a condition at which it would no longer qualify as a documentable fatality. No carcasses along the gen-tie line were monitored with cameras because of theft and vandalism concerns. Carcasses without trail cameras were visited and photographed once per day for the first four days, and then every three to five days until the end of the monitoring period. To avoid training scavengers to recognize cameras as “feeding stations”, trail cameras were installed five days before specimens were placed, and two fake cameras without bias trial carcasses were also placed within the Project fence and periodically moved to new locations within the fence. Periodic ground-based checking of carcasses with trail cameras also occurred to guard against misleading indicators of carcass removal, such as wind blowing the carcass out of the camera’s field of view. To minimize potential bias caused by scavenger swamping (Smallwood 2007, Smallwood et al. 2010), carcass-persistence specimens were distributed across the entire Project, not just in areas subject to standard searches, and trials were initiated in smaller numbers on two different dates throughout the fall season.

2.2.2 *Estimating Carcass Persistence Times*

Measurements of carcass persistence rates were subject to censoring. In this context, censoring refers to the instance when a value (e.g. days a carcass is present before being removed) may not be known exactly, but is known to be within a finite range. For example, suppose a carcass was checked on day 7 and was present, and was checked again on day 10, but was found to be missing. The exact time until removal is unknown; however, it is known that the carcass became unavailable at some point between 7 and 10 days. This carcass would be considered “interval censored”. Similarly, if a carcass lasts the entire 30-day trial period, that carcass is “right censored”— it is known that the carcass lasted at least 30 days, but it may have persisted longer. Because carcass persistence data were censored, persistence was analyzed using methods that can accommodate censored data and still produce unbiased estimates of the probability of persistence (Therneau 2015, Therneau and Grambsch 2000). It is beyond the scope of this document to provide statistical foundations of censored-data survival models but functions identical to those provided with the USGS-developed fatality estimator software (Huso et al 2012) were used to fit survival models to the censored carcass persistence data, and some background is available in the documentation provided with that software.

USGS-developed fatality estimator software (Huso et al 2012) was used to fit survival models to the censored carcass persistence data. The USGS software used to estimate carcass persistence calculates the period over which there is less than a 1% chance for a carcass to persist. The 'effective search interval' is defined as the shorter of a) the length of time beyond which there is less than a 1% probability that a carcass persists, and b) the actual search interval (Huso 2010). The probability of persistence is given for the effective search interval, and the probability that a carcass persists through the actual search interval is equal to *p* (persist through effective search interval) * effective search interval / actual search interval.

There were four distributions implemented in survival models used to estimate the probability a carcass is unscavenged and available to be found at the end of the search interval (*r)*: exponential, Weibull, loglogistic, and lognormal. These four distributions exhibit varying degrees of flexibility in order to model a wide variety of distributions of persistence time. Akaike's Information Criterion adjusted for sample size (AICc; Akaike 1973) was used to rank the fit of each survival model with combinations of the covariates carcass size, Project component, season, and visibility, to observed carcass persistence data.

2.3 Searcher Efficiency Trials

Searcher efficiency trials were conducted throughout the fall period. Carcasses from three size classes (small, medium, and large) were used for trials. The small size class comprised house sparrows and 2-3 week old coturnix quail, the medium size class comprised rock pigeons, chukar, and older coturnix quail, and the large size class comprised hen mallards and hen ring-necked pheasants.

2.3.1 *Searcher Efficiency Data Collection*

Training of biologists on the Project-specific protocol and early assessments of habitat conditions within the solar arrays suggested that the amount of cobble present in the soil may be an important factor influencing searcher efficiency. To satisfy requirements regarding consideration of visibility class per the BBCS and address the influence of cobble cover on searcher efficiency, sample units in the solar arrays and along the gen-tie were stratified by cobble cover and assigned to one of two classes (<15% and >15% cobble cover). Classes were determined by making ocular estimates of cobble cover at each sample unit and then evaluating the frequency histogram of sample units across the range of estimated cobble cover (Figure 4). A natural break point was identified at 15% cobble cover, so the same value was chosen as the break point that defined the two cobble cover classes. Thus, in the solar arrays, two sets of searcher efficiency trials were conducted (one set in each cobble cover class; total *n* = 45 small birds, 30 medium birds, and 15 large birds as agreed upon in section 7.4 of the approved Desert Sunlight BBCS). Along the gen-tie, visibility was expected to be related to vegetation and rock cover. Thus, searcher efficiency trials along the gen-tie occurred in two visibility classes (*n* for each class = 15 small birds, 10 medium birds, and 5 large birds (easy: ≥90% bare ground, vegetation <6" tall; and more difficult: <90% bare ground, vegetation ≥6" tall). Thirty searcher efficiency trials (*n* = 15 small birds, 10 medium birds, and 5 large birds) occurred along the fence in the only visibility class present on the fence (easy visibility). During fall, a total of 180 searcher efficiency trials occurred at the Project. Locations for trials were chosen by taking a randomized sample of all locations included in standardized carcass searches.

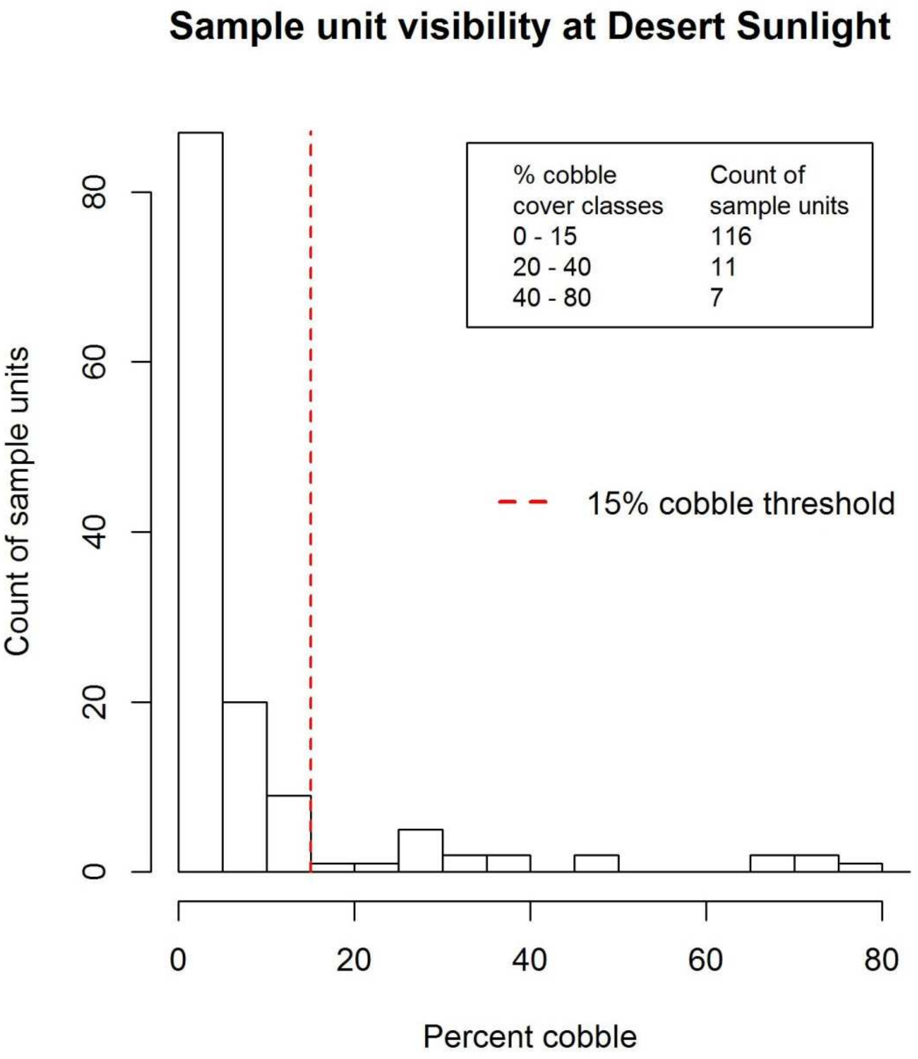

Figure 4. Frequency histogram of sample units (in the arrays only) at Desert Sunlight Solar Farm Project by estimates of cobble cover. Based on this distribution, each sample unit was assigned to one of two classes of cobble cover (<15%; >15%).

2.3.2 *Estimating Searcher Efficiency*

Searcher efficiency at Desert Sunlight was estimated separately for linear features (the project fence and the gen-tie line), and the solar arrays, reflecting the different search methods used on arrays and linear features. For linear features, logistic regression models were fit to searcher efficiency data and AICc was used to compare models. Models including effects of carcass size (three classes), visibility (two classes; gen-tie only), and season were compared to each other and the null model. Model selection indicated that the most supported model included main effects of Project component, carcass size, and season and an interaction between season and component. Once the analysis was focused on fall data only (because of the seasonal effect), the most supported model was reduced to main effects of Project component and carcass size.

Once the most supported model was chosen and appropriate classes identified, searcher efficiency, or the proportion of carcasses detected, *p*, was calculated for each class using the following equation:

$$p = \frac{Number\ of\ Carcasses\ Observed}{Number\ of\ Carcasses\ Available}$$

The data for this analysis included all searcher efficiency trial carcasses from the fall 2015 season.

For the solar arrays, searcher efficiency was evaluated using a distance sampling approach (Buckland et al. 1993). Distance sampling assumes perfect detection on the transect line (at distance = 0), an assumption that is likely valid in the solar arrays given the relatively flat & vegetation-free nature of the soil surface. A curve is fitted to the observed carcass data that predicts probability of detection as a function of distance from the transect line. The mean value of this function over a specified distance, *w,* is equal to the average searcher efficiency for a transect of width *w*. The mean value of the detection curve is the integral of the detection function calculated between 0-m and the maximum survey distance (*w;* half the width of the solar array row), divided by the maximum survey distance:

$$p = \frac{\int_0^w f(x)dx}{w},$$

where f(x) is the detection function evaluated at distance, *x*.

One departure in the methods used here, relative to the methods presented in Buckland et al. (1993), was that for this study the detection function was estimated using trial carcasses, which meant that there were both presence (detected) and absence (not detected) data available to fit the detection function (Figure 5). The availability of both presence and absence data means that the detection function can be estimated using only trial carcasses whose distribution is known. Therefore the detection function, the average searcher efficiency among the arrays, and the final fatality estimate within the arrays are all insensitive to the spatial distribution of carcasses within individual arrays, and the overall searcher efficiency estimate is valid even if the distribution of carcasses among the arrays is not uniform.

Distances of trial carcasses (trials both found and missed) from the transect line were used to fit half-normal, exponential, and hazard rate distribution detection functions for searches among the arrays, which are all commonly used functions for distance sampling surveys (Buckland et al. 1993). The fit of detection functions were compared using AICc and each model was fit with covariates (season, carcass size, cobble cover class), and without. The most supported detection function had an exponential distribution and the most supported among these models included an interactive effect of carcass size and season.

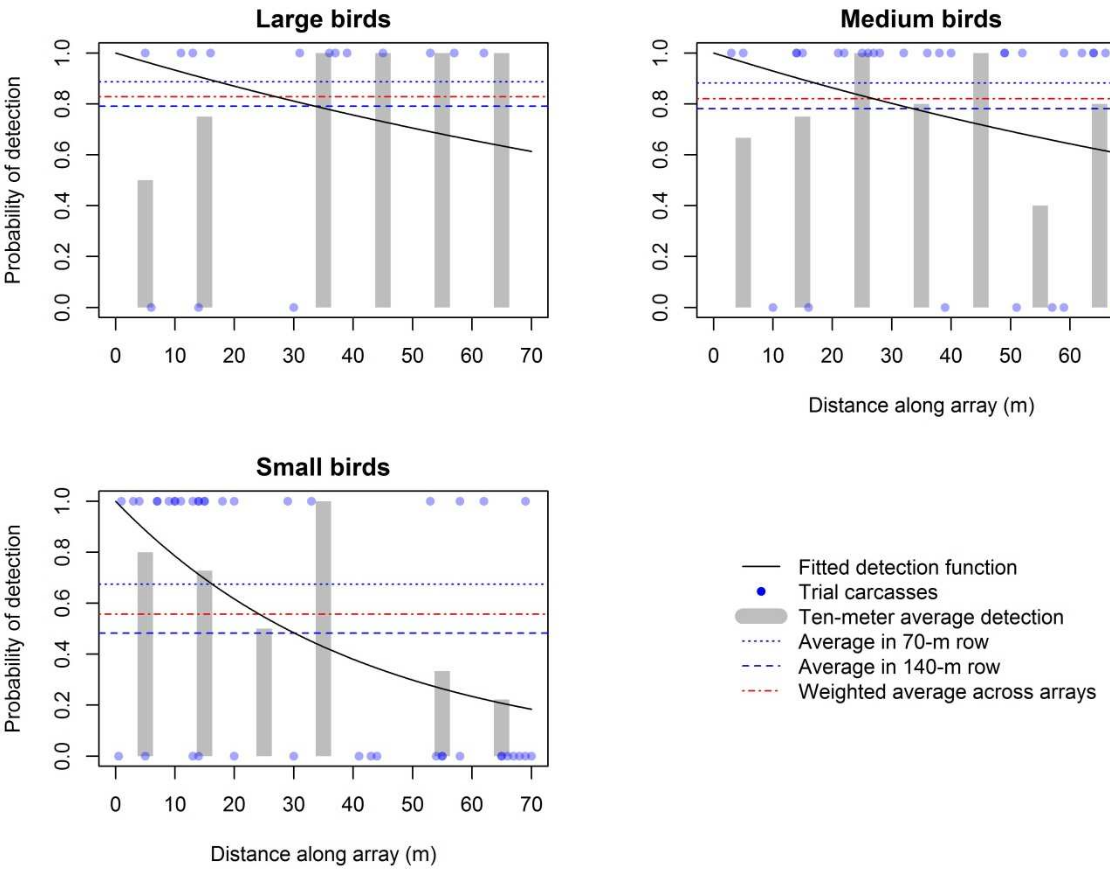

Figure 5. Estimated detection probabilities for bird carcasses by size class during fall (August 31 – October 31) 2015 at the Desert Sunlight Solar Farm Project, Riverside County, California. Distance sampling was used when searching solar arrays only. Average probability of detection over 70-m (arrays relying on a 35-m viewshed) and 140-m (arrays relying on a 70-m viewshed) panel rows in solar arrays are presented.

Because the solar arrays were surveyed by searchers who walked down both sides of the rows of panels, the width of the search transect was specified as half the width of the rows of panels. For larger birds, there is almost certainly a non-zero detection probability beyond this distance but the bias that occurs by ignoring this non-zero detection probability is conservative (i.e. the searcher efficiency is underestimated). Some solar arrays have row widths of 70 m (search transect width of 35 m) and some have row widths of 140 m (search transect width of 70 m). The weighted average searcher efficiency is calculated based on the number of panel rows of each length in the survey sample:

$$p_{weighted\ average} = \frac{n_{70}}{n} \times \frac{\int_0^{35} f(x)dx}{35} + \frac{n_{140}}{n} \times \frac{\int_0^{70} f(x)dx}{70},$$

where n_{70} is the number of 70-m rows in the sample, n_{140} is the number of 140-m rows in the sample, and *n* is the total number of rows in the sample. Searcher efficiency was higher for the arrays with a width of 70 m, and overall searcher efficiency was estimated as a weighted average based on the proportions of 70-m arrays and 140-m arrays in the sample units.

2.4 Fatality Estimator

Fatality rate estimation is a complex task due to several variables inherent to every fatality monitoring study. Carcasses may persist for variable amounts of time due to local scavenger activity or environmental conditions leading to carcass degradation over time. Carcasses and feather spots are also detected with varying levels of success based on carcass characteristics and ground cover (e.g., vegetated areas underneath the gen-tie line versus cleared areas beneath solar panels). For these reasons, it is generally inappropriate to draw conclusions based on the raw number of fatalities alone. The desire to estimate fatalities given these variables has driven the development of several statistical methods for estimating fatalities (e.g., Smallwood 2007, Huso 2010, Korner-Nievergelt 2011). All of these fatality estimation methods share a similar underlying model. Generally, the fatality estimation for a given site may be written as:

$$F=C/rp,$$

where F is the total number of fatalities, C is the number fatalities detected and included in fatality estimation, r is the probability a carcass is unscavenged and available to be found at the end of the search interval, and p is the probability of detecting a carcass (Huso 2010). Huso (2010) describes the use of a binomial model to estimate the probability of carcass detection; in the present study, the binomial carcass detection model was used to calculate fatalities at project linear features (fence, overhead lines), and the weighted average probability of detection based on distance sampling (described above) was used to estimate probability of detection within the solar arrays.

.

All fatality estimates were calculated using the Huso estimator estimator (modified to accommodate the distance-sampling based estimate of searcher efficiency in the solar arrays), as well as 90% confidence using bootstrapping (Manly 1997). Bootstrapping is a computer simulation technique that is useful for calculating point estimates, variances, and confidence intervals for complicated test statistics. A total of 1,000 bootstrap replicates was used for each variable including of searcher efficiency (p), probability of a carcass persisting to the next search $(\hat{r})$, adjusted search interval and observed fatalities. From these bootstrap samples, the probability of available and detected was calculated and applied to the bootstrapped observed fatalities. The lower 5th and upper 95th percentiles of the 1,000 bootstrap estimates provide estimates of the lower limit and upper limit of an approximate 90% confidence interval on all estimates.

2.5 Incidental Reporting

Some detections were outside standardized search areas, or were within search areas but not observed during standardized searches. Such detections were found by WEST avian biologists and operational personnel and were considered “incidental” detections. When found by operational personnel, these detections were reported to WEST avian biologists for documentation. Data on incidental detections are reported here, as well as in the Desert

Sunlight SPUT Avian Injury and Mortality Report Forms August - October 2015. All detections made in search areas during the reporting period were included in fatality estimates, regardless of whether they were detected incidentally or during searches.

3.0 MONITORING RESULTS

3.1 Summary of Avian Detections

During fall 2015, a total of 83 avian detections (including incidentals) of 38 identified species were recorded (Table 3). The most common identified species was American coot (*Fulica americana*) with 11 detections. Most detections (n = 54, or 65.1% of total detections) occurred in the solar arrays (Figures 2 and 3; Tables 4, 5, and 6). Sixty-two (74.7%) detections occurred during standardized carcass searches and 21 (25.3%) were documented as incidentals. No bats were detected during the fall season. For fresh carcasses, body weights and weather conditions the preceding nights are described in Appendix B.

[1] Ring-necked pheasants are used for bias trials and these two detections were likely from trial carcasses; however, ring-necked pheasants have been reported in Riverside County, CA south of the Project area near the Salton Sea (eBird 2015). Thus, we cannot be certain that these detections were exclusively from trial carcasses.

[2] See literature cited for migration behavior references; information for most species was taken from the respective species accounts found in Birds of North America (BNA) Online (http://bna.birds.cornell.edu/bna/); where information on migration behavior was lacking in BNA accounts, Newton (2008) or Murray (2004) were used.

Table 4. Total avian detections by Project component and detection category during fall (August 31 – October 31) 2015 at the Desert Sunlight Solar Farm Project, Riverside County, California. Only carcasses found within search areas were included in fatality estimates.

	Inside carcass search area		Outside carcass search area	
Project Component	**Carcass search**	**Incidental**	**Carcass search**	**Incidental**
Fence	0	0	0	0

Solar arrays				
Line-associated	4	1	1	3
Non-line associated	28	5	1	11
Total	**55**	**6**	**7**	**15**

Table 5. Total avian detections (including incidentals) by Project component and suspected cause of death during fall (August 31 – October 31) 2015 at the Desert Sunlight Solar Farm Project, Riverside County, California.

	Suspected Cause of Death*				
Project Component	**Collision**	**Predation**	**Other**	**Unknown**	**Percent of Total**
Fence	0	0	0	0	0.0
Visitor Center	0	0	0	1	1.2
Gen-tie line	9	1	0	18	33.7
Solar arrays					
Line-associated	2	0	0	7	10.8
Non-line associated	6	0	1	38	54.2
Percent of Total	**20.5**	**1.2**	**1.2**	**77.1**	**100.0**

* Suspected cause of death was assigned based on evidence available on the detection, evidence available on Project infrastructure, and proximity of detection to Project infrastructure. Detections that had evidence of scavenging and lacked evidence on Project infrastructure were assigned as "unknown" because it can't be determined whether the event was caused by predation or interaction with project infrastructure. Detections that were intact (i.e., no evidence of scavenging) and located in close proximity to Project infrastructure (e.g., found directly beneath overhead lines) had a suspected cause of death attributed to the respective Project component. However, there is substantial uncertainy associated with cause of death assignments because no events were directly observed.

3.2 Temporal Patterns of Avian Detections

The number of detections recorded daily during the reporting period ranged from zero to six, and were more or less evenly distributed throughout the season (Figure 6). Daily detections peaked on September 22 and this event was reported to the agencies per Special Purpose Utilities Permit Condition H(c). The number of detections per day represents those discovered during standardized carcass searches and incidentally.

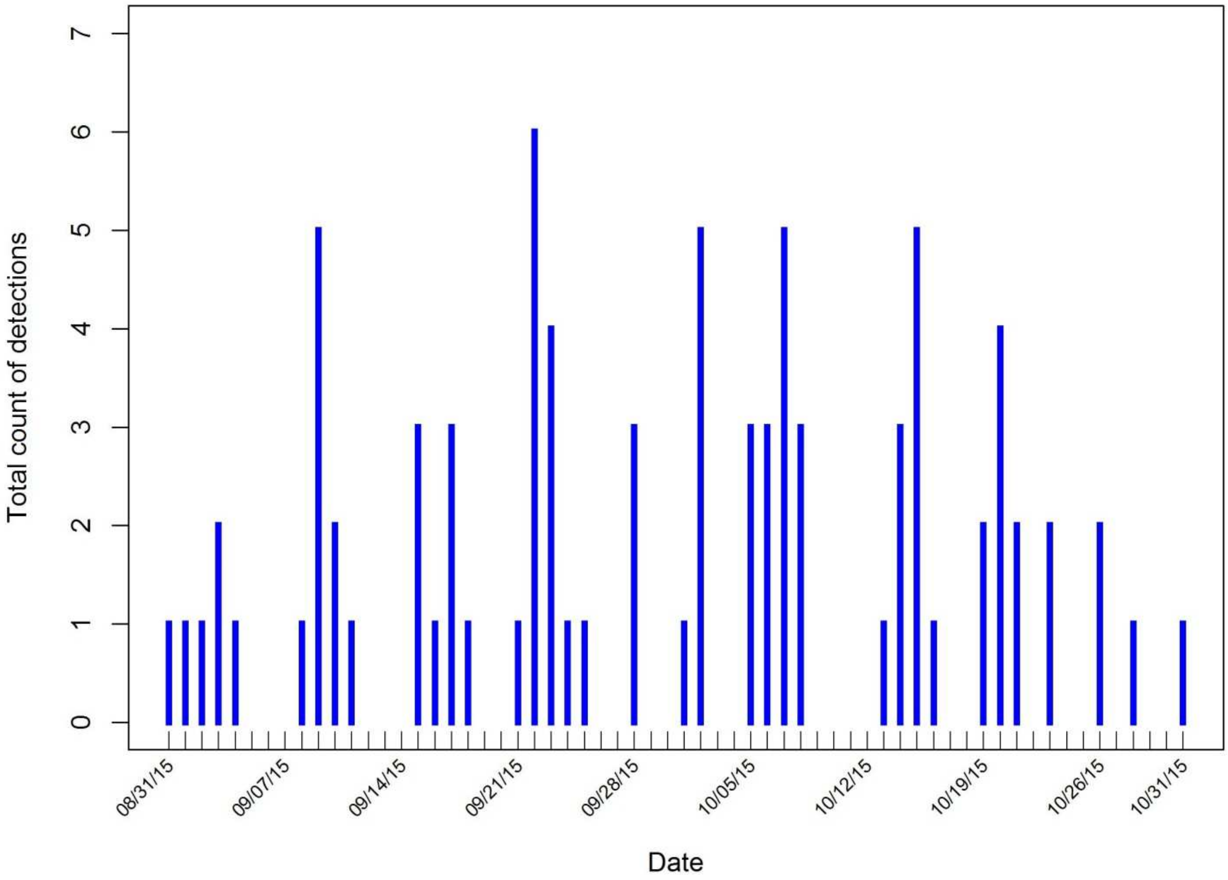

Figure 6. Total count of detections (including incidentals) by date during fall (August 31 – October 31) 2015 at the Desert Sunlight Solar Farm Project, Riverside County, California.

3.3 Spatial Distribution of Avian Detections

3.3.1 *Detections by Project Component*

During the reporting period, detections were documented from the solar arrays, the Visitor Center, and the gen-tie line; no detections occurred at the Visitor center or along the fence (Tables 3, 4, and 5). Of the 54 detections within the solar arrays, 16.7% (9) were associated either with overhead lines or arrays that co-occurred with overhead lines. Twenty-eight detections (33.7% of season total) were along the gen-tie line, and one detection (1.2% of season total) was at the Visitor Center.

3.3.2 *Feather Spot Detections*

Fourteen (16.9%) of the 83 detections made during fall consisted only of feather spots. Along the gen-tie, nine of 28 detections (32.1%) were feather spots. Five of 54 detections (9.3%) in the solar arrays were feather spots. There were no detections along the fence during fall.

3.4 Detections of Injured or Stranded Birds

There were six injured or stranded birds detected during fall 2015. Three injured birds were detected at line-associated (ruddy duck [*Oxyura jamaicensis*]) and non-line associated arrays (2; mourning dove [*Zenaida macroura*] and western grebe [*Aechmophorus occidentalis*]). Three stranded but uninjured birds were detected at line-associated (common loon [*Gavia immer*]) and non-line associated (ruddy duck and eared grebe [*Podiceps nigricollis*]) arrays. The injured mourning dove and ruddy duck were transported to wildlife rehabilitation facilities; the ruddy duck was released by the rehabilitator on the same day. The injured western grebe died before it got to a rehabilitation facility. The stranded ruddy duck, eared grebe, and common loon were evaluated for a short period for injuries and general stress and when none were observed, released at Lake Tamarisk. Three detections of injured or stranded birds were included in fall fatality estimates; three were excluded because they were found outside of a standardized carcass search area.

3.5 Summary of Bat Detections

No bats were detected during the fall 2015 season.

3.6 Carcass Persistence Trials

Data from carcass persistence trials were available from late winter, spring, summer, and fall at the solar field and gen-tie line (n = 215 total). Based on carcass persistence data from all seasons so far in 2015, survival models were compared for relative quality using the corrected AICc score, as suggested in Huso (2010). The AICc score provides a relative measure of model fit and parsimony among a selection of candidate models, and provides a framework for testing hypotheses regarding which factors contribute to carcass persistence rates. Carcass size was tested as a potentially important variable, as larger carcasses tend to persist longer and may be more likely to leave feather spots which persist for long durations, whereas smaller carcasses may be more likely to be completely removed. Project component (solar arrays, gen-tie line) was also included as a potentially important variable, as was season.

The model with lowest AICc score is typically chosen as the “most supported” model relative to other models tested; however, any model within two AICc points of the most supported model is considered competitive with the most supported model (Burnham and Anderson 2004). Preliminary modeling suggested a main effect of season, so further modeling efforts were restricted to data collected in fall only. The most supported model using only the fall data included main effects of carcass size and Project component, with a removal time that was lognormally-distributed (Appendix C). Estimates of carcass removal time and persistence probabilities from the most supported model are reported in Table 6, and estimates of proportion of carcasses remaining as a function of days since carcass placement are provided in Figure 7. Detailed estimates of carcass removal and associated confidence intervals are provided in Appendix C.

Table 6. Mean and median carcass removal time and probability of a carcass persisting through the effective search interval during the fall (August 31 – October 31) 2015 season at the Desert Sunlight Solar Farm Project, Riverside County, California.

Carcass size	Project component	Mean removal time (days)	Median removal time (days)	Probability of persistence
Small	Arrays/fence	2.2	1.5	0.46
Small	Overhead lines	0.1	0.5	0.08
Medium	Arrays/fence	17.4	16	0.80
Medium	Overhead lines	0.8	1.5	0.30
Large	Arrays/fence	203.3	30	0.98
Large	Overhead lines	9.7	3.5	0.72

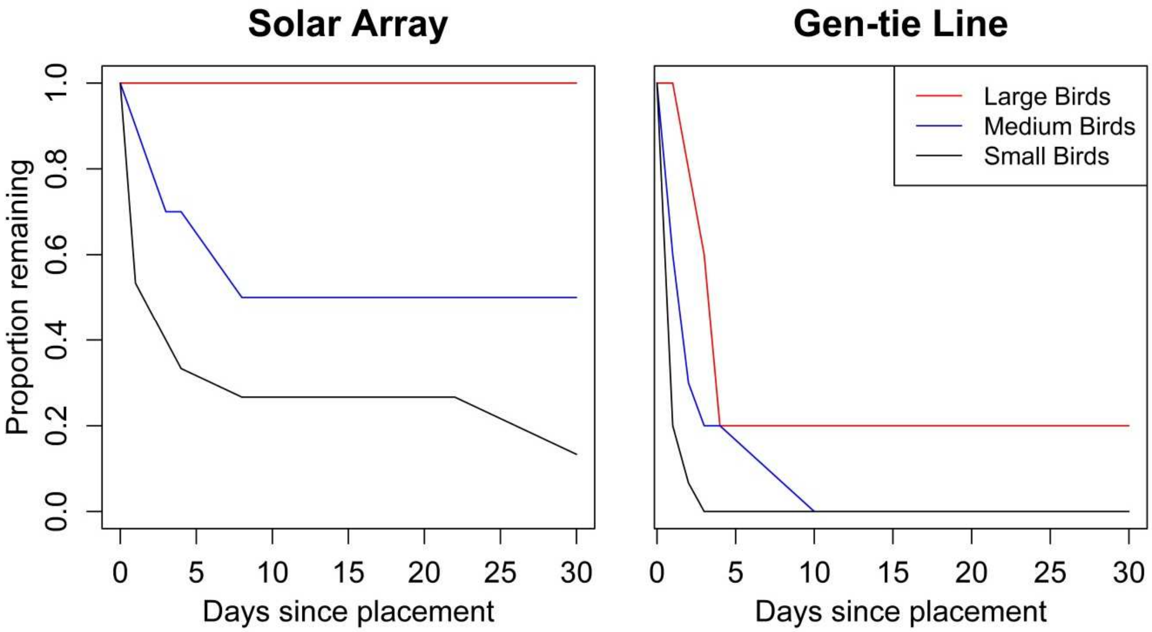

Figure 7. Proportion of trial carcasses remaining as a function of days since placement and carcass size class (n = 30, 20, and 10 for small, medium, and large size classes, respectively) during the fall (August 31 – October 31) 2015 season at the Desert Sunlight Solar Farm Project, Riverside County, California.

3.7 Searcher Efficiency Trials

During the reporting period, a total of 180 searcher efficiency trials were placed at the Project. Most trials were available to be found, but some disappeared before or during the trial. Overall, 90 trials were placed in the solar arrays and 87 were available to be found; 30 trials were placed along the perimeter fence (inner perimeter only) and 29 were available to be found; and 60 trials were placed along the gen-tie line and 51 were available to be found. Three observers conducted searches at the Project during fall. Searcher efficiency trials were conducted on each observer in approximate proportion to the number of searches they conducted at the Project, as follows: Sarah Nichols (number of trials available to be found: 28), Darin Blood (62), and Wanda Bruhns (77). All trials were included in estimation of searcher efficiency.

In the solar arrays, the model that included an effect of carcass size was chosen as the most supported model to estimate searcher efficiency (Appendix C). Within the solar arrays, searcher efficiency was: 55.7% for small birds, 82.1% for medium birds, and 82.9% for large birds (Figure 5; Appendix C).

For linear Project components, the model that included an effect of carcass size, Project component, and season was chosen as the most supported model to estimate searcher efficiency. Along the fence, searcher efficiency was 90.1% (CI: 78.1 – 100%), 94.9% (CI: 86.2 – 100%), and 98.0% (CI: 92.6 – 100%) for small, medium, and large carcasses, respectively. Along the gen-tie, searcher efficiency was 44.7% (CI: 27.4 – 62.4%), 62.5% (CI: 45.5 – 80.0%), 81.0% (CI: 60.0 – 100%) for small, medium, and large carcasses, respectively. Detailed estimates of searcher efficiency estimates specific to each component and carcass size are reported in Appendix C.

3.8 Fatality Estimates

Fatality estimates were calculated separately for each component (solar arrays, fence, and overhead lines). Ultimately, 22 detections were excluded from the fatality analysis because they were found outside standardized search areas (Table 47; Appendix C). All 83 detections ~~made~~ that occurred during fall are reported in Table 3.

Table 7. Status of detections during the fall (August 31 – October 31) 2015 season at the Desert Sunlight Solar Farm Project, Riverside County, California. All detections outside the search area were excluded from the fatality analysis, regardless of whether they occurred during a standardized carcass search or incidentally.

	Carcass search	Incidental detection	*Pushed to next season's fatality estimate	*Pulled from previous season's fatality estimate
Inside search area	55	6	0	0
Outside search area	7	15	0	0

* Incidental detections occurring after the last standardized carcass search in a season are considered for inclusion in the fatality analysis for the following season. This is consistent with the assumption we make throughout the monitoring seasons; that carcasses found incidentally would have been available to be found on the next scheduled search. This assumption may result in some carcasses found during one season but considered in the following season's fatality analysis. Once a carcass has been moved to a different season's analysis it is still subject to the same criteria for inclusion or exclusion based on location (in versus out of a searched area) and carcass age (greater than versus less than the search interval).

During fall 2015, 296 carcasses (90% CI: 198 – 461) were estimated for the solar arrays. There were an estimated 0.115 carcasses per acre (within the solar field only; 296 estimated carcasses/2,585 acres) and an estimated 0.538 carcasses per nameplate MW (296 estimated carcasses/550 MW) within the solar field.

Estimates of fatalities along the gen-tie are heavily influenced by the high rates of scavenging observed during the limited trials at the gen-tie (i.e., large correction factors) and are likely very unreliable. The estimate along the gen-tie was 894 carcasses (90% CI: 362 – 2,948). No carcasses were estimated for the perimeter fenceline because there were no detections made along the fence. A complete list of estimates for each Project component and carcass size class with confidence intervals is presented in Appendix C.

4.0 DISCUSSION

The 2015 fall season represented the third full season of standardized monitoring at Desert Sunlight per the BBCS. Searcher efficiency and carcass persistence trials were conducted concurrently at the solar arrays, fencelines, and along the gen-tie line. Data from these trials were used to produce fatality estimates adjusted for searcher efficiency and carcass persistence bias. Although these estimates were produced from a statistically robust sample, only limited inference may be drawn from three seasons of data. These results should be considered preliminary because estimating carcass persistence, searcher efficiency, and adjusted numbers of fatalities within each season represents information based on a limited sample size. As more data are collected throughout the monitoring year (and additional quality assurance/quality control measures occur, for example characterizing feather spots to species or size class), data from all seasons may be pooled. At that time, data will be tested for seasonal differences retrospectively, but because seasonal estimates will be produced from the much larger annual data set, they may differ from what is reported here because they are based on a larger, more informative sample.

4.1 Carcass Persistence and Searcher Efficiency Trials

The degree to which carcasses persist on the landscape depends on a variety of factors reflecting seasonal and inter-annual variation in habitat, climate, and the scavenger community. The composition and activity patterns of the scavenger community often vary seasonally as birds migrate, new juvenile birds and mammals join the local population, and mammalian scavengers variably hibernate or estivate. The scavenger community may also vary substantially from year to year because of variation in annual reproduction and survival related to changes in landscape condition. Climatic conditions that vary seasonally and annually also may contribute to variation in carcass decay and removal rates due to variation in temperatures, solar insolation, wind patterns, and the frequency of flooding events. Thus, rates of carcass persistence reported here should be interpreted cautiously as they may change over the coming months.

Fatality estimates are influenced by the relationship between carcass removal dynamics and search intervals. In practical terms, longer search intervals reduce average probability that a carcass persists until the next search. In terms of the analysis, this can manifest as a lower probability of persistence through the effective search interval, or an effective search interval that is shorter than the nominal search interval. In either case, the adjustment to carcass counts due to carcass removal dynamics is calculated as

$$\frac{length\ of\ effective\ search\ interval}{length\ of\ nominal\ search\ interval * average\ probability\ of\ persistence\ through\ the\ effective\ search\ interval}$$

The adjustment to estimated fatality for carcass removal increases with longer search intervals, and the variance in the estimate may increase, also.

Carcass persistence at the Project is clearly influenced by whether a carcass is located in the solar field (inside the perimeter fence) or along the gen-tie (outside the perimeter fence), with higher removal rates occurring along the gen-tie. Although the same scavenger species may occur at both Project components, a difference in scavenger density or activity between the components could possibly be responsible for the different rates of carcass persistence. If there are differences in scavenging rates between the trial carcasses and naturally-occurring carcasses, it is possible that the high scavenging rates observed along the gen-tie have resulted in inflated fatality estimates. This hypothesis may be evaluated in the annual report by comparing persistence rates of trial carcasses to the age of carcasses detected by observers. Given the very high scavenging rates along the gen-tie line, fatality estimates for the gen-tie are unreliable.

Searcher efficiency was influenced by Project component, carcass size, and season. In the solar arrays, searcher efficiency was high (>0.5) for all carcass size classes and this is likely influenced by the limited vegetation cover beneath solar panels. Beneath the gen-tie line, vegetation cover is higher in some portions of the strip transects, but results reported here support the hypothesis that visibility class was not a factor in searcher efficiency along the gen-tie line during fall. Placement of trial carcasses in both difficult and easy visibility classes ensures that the adjustment due to searcher efficiency accounts for both visibility classes, even if there is a real difference in searcher efficiency that cannot be detected with the trial data.

4.2 Distribution of Fatalities and Fatality Estimates

Detections were distributed throughout the fall season, and there were no clear peaks in detections associated with a particular date or range of dates. Tapering of daily detections at the beginning and end of the fall season (Figure 6) suggests that the current dates that define the season likely capture the majority of fall migration at the Project.

Most (65.1%) of the 83 detections made during fall were in the solar field. Approximately 13% of the carcasses found in search plots had overhead lines associated with those plots and 10% of the plots searched had lines associated with them, suggesting overhead lines within the solar field may not influence mortality. The absence of any detections along the fence in fall coupled with the very low number of detections in previous seasons (spring: 2; summer: 1) and relatively high carcass persistence rates inside the fence suggest the perimeter fence at the Project may not be an important source of mortality.

Composition of detections during fall 2015 included 13 avian guilds. Waterbirds and waterfowl comprised the majority of detections (n = 21), followed by rails and coots (n = 13), grassland birds and sparrows (n = 12), and warblers (n = 10). All other guilds were represented by fewer than ten detections. No bats have been detected since monitoring began at the Project. Species that migrate nocturnally were detected most frequently during fall (n = 21 species). Ring-necked pheasants were included in the list of detected birds (Table 3), but these detections were most likely from trial carcasses. However, because ring-necked pheasant have been reported in

Riverside County, CA (eBird 2015) south of the Project area near the Salton Sea, we could not be certain that both detections were from trial carcasses.

Detections attributed to an unknown cause accounted for 77.1% of all detections during the reporting period, and most of those attributed to an unknown cause were found in the solar arrays. Of the 54 detections made in the solar arrays, 11.1% were feather spots. Determining a cause of mortality from a feather spot is challenging because there is rarely visible evidence available on which to determine a cause of death. Thus, feather spots with an unknown cause of mortality could be encountered anywhere birds occur, and an unknown cause of a sizeable proportion of the carcasses is not unique to the Project. Further, the relatively large proportion of feather spots (18.1%) among the detections for the Project as a whole may inflate the fatality estimate based on the potential for multiple feather spots resulting from one fatality, feather spots resulting from predation not associated with the facility, or other causes.

EXECUTIVE SUMMARY

Avian and bat monitoring surveys were conducted from August 31 to October 31, 2015 (the fall reporting period) at Desert Sunlight Solar Farm Project (Project) in accordance with the Project's Bird and Bat Conservation Strategy (BBCS). Specifically, standardized carcass searches, searcher efficiency trials, and carcass persistence trials were conducted. This report represents the third seasonal report for the first year of monitoring, and summarizes monitoring methods and results for those surveys based on the procedures and requirements specified in the BBCS. This report and the other interim quarterly reports are considered preliminary summaries of data and information. Data and final information from all four quarterly monitoring periods will be included in a comprehensive final annual report.

Included in this report are data from standardized carcass searches conducted during the fall season at the Project, defined as August 31 to October 31, 2015. For logistical reasons, fall monitoring began on Monday, August 31, 2015. Standardized carcass searches were conducted 1) in the solar field, consisting of a random stratified 29.5% sample of solar photovoltaic (PV) panels, 2) along inner portions of the fenceline, resulting in 74.4% of the length of the perimeter fence, and 3) along 47.9% of the total length of generation-tie (gen-tie) line from the Project fence to the Red Bluff Substation located south of Interstate 10 (I-10). Searches conducted within the fall season had intervals of approximately seven days.

All bird and bat fatalities and injuries that were discovered by observers, referred to as "detections" in this report, including those found incidentally and during standardized carcass searches, were documented. During the reporting period, there were 83 avian detections, and there were no detections of bats.

According to specifications of the BBCS, avian detections were categorized by likely diurnal or nocturnal migration behavior, ecological guild (e.g., raptors, songbirds, etc.), facility component, and suspected cause of death. These standardized carcass search results, along with searcher efficiency and carcass persistence rates from bias trials conducted on site, were applied to a fatality estimator model (Huso 2010) to provide a preliminary estimate of the number of fatalities that occurred at the Project during the reporting period adjusted for sources of bias. The estimate is considered preliminary because the annual report may pool information from bias trials and other data across seasons which could affect seasonal estimates.

During the reporting period, carcass persistence was influenced by carcass size and Project component. Small carcasses (0-100 g) in the arrays and along the fence (combined) had a 46% chance (90% confidence interval [CI]: 30 – 63%) of persisting through the effective search interval, medium carcasses (101 – 999 g) had a 80% (64 – 92%) chance, and large carcasses (1000+ g) had a 98% (95 – 100%) chance. Mean (median) removal time within the arrays for small, medium, and large carcasses was 2.2 (1.5), 17.4 (16), and 203.3 (>30) days, respectively. Along the gen-tie line, chances of persistence for small, medium, and large carcasses were 8% (3 – 14%), 30% (17 – 43%), and 72% (58 – 87%), respectively; mean

Comentado [FWS1]: Please include median removal times and n for each size class.

Comentado [WEST2]: added

(median) removal time for small, medium, and large carcasses was 0.1 (0.5), 0.8 (1.5), and 9.7 (3.5) days, respectively. Sample sizes for each stratum were contained to fall trials only and included 15, 10, and 5, small, medium and large bird carcasses respectively. Within the solar arrays, searcher efficiency was influenced by carcass size: 55.7% for small birds, 82.1% for medium birds, and 82.9% for large birds. The sample size included trials from fall and was composed of 45 small, 30 medium and 15 large birds. Along the interior of the fence, searcher efficiency ranged ~~was~~ from 90.1% (CI: 78.1 – 100%), 94.9% (CI: 86.2 – 100%), and 98.0% (CI: 92.6 – 100%) for small, medium, and large carcasses, respectively. Along the gen-tie line, searcher efficiency ranged from 44.7% (CI: 27.4 – 62.4%), 62.5% (CI: 45.5 – 80%), and 81.0% (CI: 60.0 – 100%) for small, medium, and large carcasses, respectively. Searcher efficiency estimates along the gen-tie were informed by a sample size of 30, 20, and 10 bird carcasses respectively, placed during the fall season.

Comentado [FWS3]: Add median removal times and n for each size class.

Comentado [WEST4]: added

Comentado [FWS5]: Please include n for each size class.

Comentado [WEST6]: added

Composition of detections during fall 2015 included 13 avian guilds. Waterbirds and waterfowl comprised the majority of detections (n = 21), followed by rails and coots (n = 13), grassland birds and sparrows (n = 12), and warblers (n = 10). All other guilds were represented by fewer than ten detections. No bats have been detected since monitoring began at the Project. Species that migrate nocturnally were detected most frequently during fall (n = 21 species).

During fall 2015, 296 carcasses (90% CI: 198 – 461) were estimated for the solar arrays. There were an estimated 0.115 carcasses per acre (within the solar field only; 296 estimated carcasses/2,585 acres) and an estimated 0.538 carcasses per nameplate MW (296 estimated carcasses/550 MW) within the solar field.

Estimates of fatalities along the gen-tie are heavily influenced by the high rates of scavenging observed during the limited trials at the gen-tie (ie. large correction factors) and are likely very unreliable. The estimate along the gen-tie was 894 carcasses (90% CI: 362 – 2,948). No carcasses were estimated for the perimeter fenceline because there were no detections made along the fence.

1.0 INTRODUCTION

1.1 Project Background

Desert Sunlight 250, LLC and Desert Sunlight 300, LLC (collectively, Desert Sunlight) constructed and operates the Desert Sunlight Solar Farm Project (referred to in this report as "Project"), which consists of two main components: 1) a 550-megawatt (MW) photovoltaic (PV) generating facility; and 2) a 220-kilovolt (kV) generation interconnection (gen-tie) line. The Project comprises approximately 1,700 hectares (ha; 4,200 acres) of land administered by the Bureau of Land Management (BLM) six miles north of Desert Center in Riverside County, California (Figure 1).

1.2 Monitoring Plan Overview and Goals

A Bird and Bat Conservation Strategy (2014; “BBCS”) was prepared by the Project proponent in collaboration with the U.S. Fish and Wildlife Service (USFWS), California Department of Fish and Wildlife (CDFW), and BLM to guide comprehensive monitoring of impacts to birds and bats associated with operation of the Project. Final agency approval of the BBCS occurred in December 2014. Amendments to the sampling protocol along some portions of the Project fenceline were made by Desert Sunlight and approved by the BLM on February 11, 2015.

The BBCS details post-construction monitoring to be conducted and the data analysis and reporting processes that will be implemented by Desert Sunlight in collaboration with the USFWS, CDFW, and BLM. As identified in the BBCS, they are:

1. Estimate overall annual avian fatality rate and species composition associated with the Project infrastructure. This estimate will include mortality associated with solar arrays, overhead lines including the gen-tie line, perimeter fence and other features of the Project that may result in injury and fatality.
2. Determine whether there are spatial and temporal/seasonal patterns of mortality associated with project infrastructure (e.g., different fatality rates near panels on the edge of the arrays vs. the interior area of the arrays).
3. Provide information that will assist the BLM in consultation with the USFWS in understanding which species and potentially which regional populations are at risk.
4. Collect data in such a way that the BLM in consultation with the USFWS may make comparisons with other solar sites.

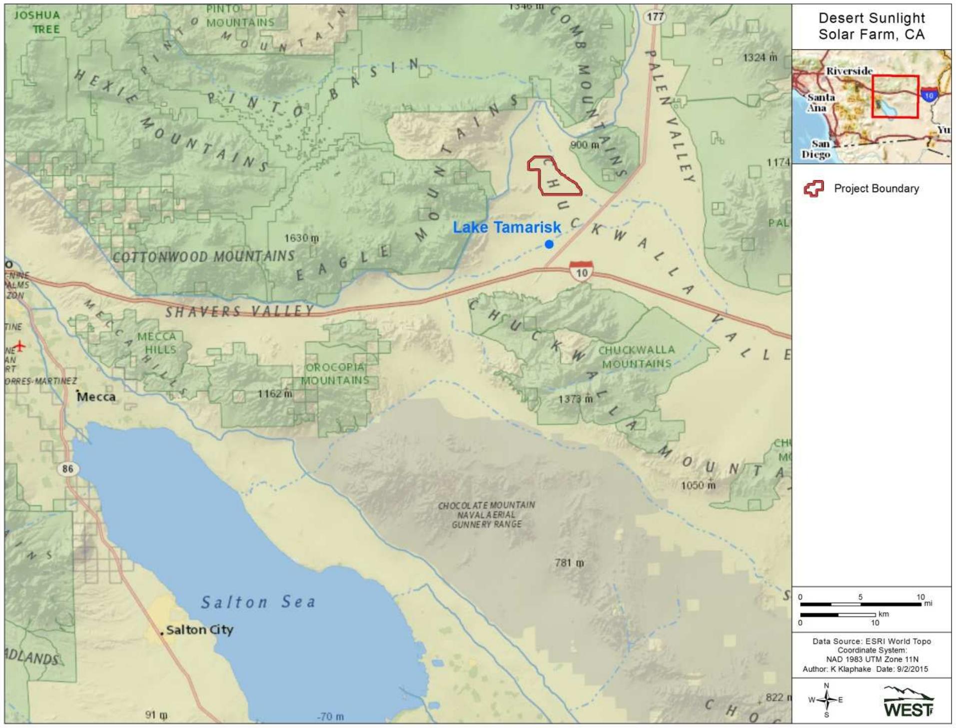

Figure 1. Desert Sunlight Solar Farm Project vicinity map, Riverside County, California.

1.3 Purpose of This Report

This report represents the third seasonal report for the first year of monitoring summarizing monitoring methods and results for avian and bat fatalities and injuries based on the procedures and requirements specified in the approved BBCS. This and the other interim quarterly reports are considered preliminary summaries of data and information. Data and final information from all four quarterly monitoring periods will be included in a comprehensive final annual report.

This report covers the period August 31 to October 31, 2015, or the 2015 fall season. For logistical reasons, fall monitoring began on Monday, August 31, 2015. All carcasses and injuries that were discovered by observers are referred to as “detections” in this report. As stated in the approved BBCS, this seasonal report includes the observed detections for likely diurnal, and likely nocturnal species, and for ecological guilds of interest (e.g., raptors, water-associated birds, passerines), for each of the facility types and suspected causes of death. Species composition of detections and the results of the bias trials are also reported. This report presents information related to the spatial distribution of detections, but no formal statistical analysis of the spatial distribution of carcasses will be conducted until the end of the monitoring year, given the limited data presently available.

2.0 METHODS

The BBCS describes the methods by which monitoring and certain analyses, including compilation of the overall fatality estimate, will occur. Below is an abridged description (see BBCS for detailed methods).

2.1 Standardized Carcass Searches

This section describes areas surveyed, the timing and frequency of searches, and the methods by which standardized searches were conducted to identify dead/injured birds and bats at the Project. Dead or injured birds and bats are called detections in this report to provide consistency in naming. This section also describes the methods for conducting carcass removal and searcher efficiency trials; how data were reported and analyzed; and the methods for producing fatality estimates for the Project.

2.1.1 *Areas Surveyed*

Standardized carcass searches were conducted at sampling units, which include the solar arrays (Table 1, 2; Figure 2); the "fenceline" defined as the perimeter fence for the Project (Table 1, Figure 2); and the gen-tie line (from the Project fence to the Red Bluff Substation on the south side of I-10; Table 1, Figure 3). Some overhead lines co-occur with solar arrays (medium voltage overhead lines [MVOH]). The MVOH were part of standardized carcass searches to the extent that they co-occured with solar arrays included in the sample (Table 2; Figure 2).

Table 1. Areas included in standardized carcass searches at the Desert Sunlight Solar Farm Project during fall (August 31 – October 31) 2015.

Project Component	Total Size	Units	% of Component Searched
Solar arrays	1045.9	Hectares	29.5[1]
Fence	16.7	Kilometers	99.0[2]
Gen-tie line	19.2	Kilometers	47.9[3]

[1] Percent area that was searched in fall 2015. Slightly less than 30% total because of unequally-sized arrays.

[2] 74.4% of the fence is fully accessible and surveyed following the standard protocol, while approximately 25% of the fence is surveyed from a distance. Fatality rates estimated for sections of the fence that are sampled were extrapolated to sections of the fence where the standard monitoring protocol cannot be used, as described in section 4.2.6 of the approved Desert Sunlight BBCS. A very short segment near the gate is not sampled due to restoration activities.

[3] 52.1% of the gen-tie will be sampled in 2016.

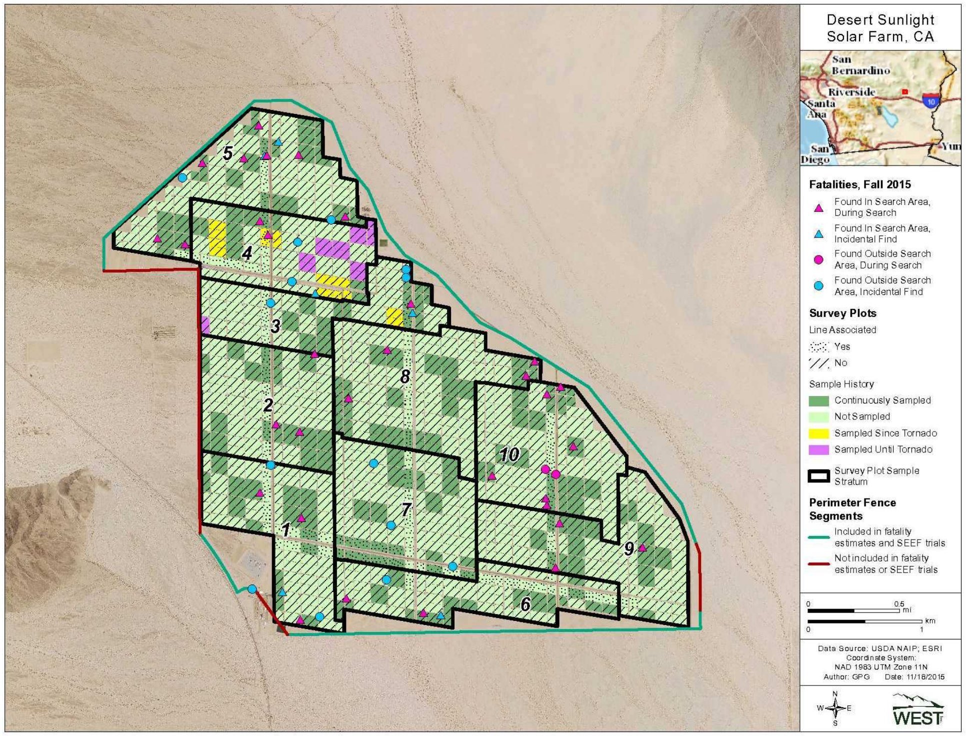

Figure 2. Areas of standardized searches and detections (those made during searches and those made incidental to operations and maintenance) at the solar field, visitor center, and overhead lines within the fence at Desert Sunlight Solar Farm Project during fall (August 31 – October 31) 2015. No detections occurred along the fence during fall 2015. The detection that appears at the fence in the map was located at the visitor center.

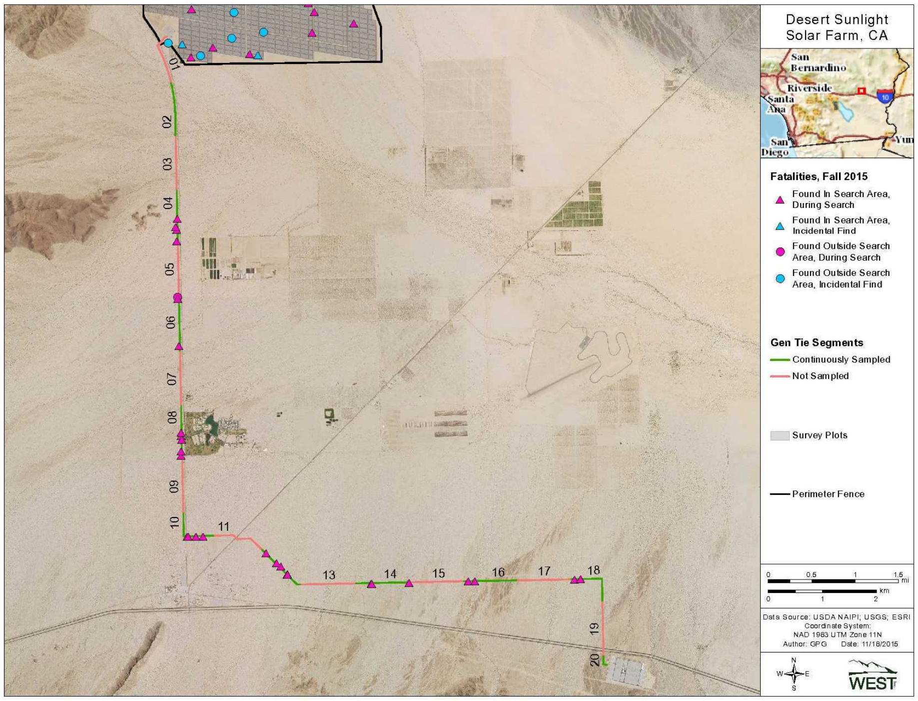

Figure 3. Areas of standardized searches and detections (those made during searches and those made incidental to operations and maintenance activities) along the generation tie line at the Desert Sunlight Solar Farm Project during fall (August 31 – October 31) 2015. Detailed maps of detections along the line are presented in Appendix A.

To ensure a balanced distribution of sample units in the solar field (defined as the collection of all photovoltaic [PV] solar panels), the entire field was divided into ten strata, and individual sampling units were randomly selected within each stratum to compose an approximately 30% sample. This sampling design ensures that units included in the sample were not spatially clumped within the solar field. The solar field consists of arrays of solar panels (referred to as a solar array) that are either 70-m or 140-m wide. The sample includes 133 of each type of array. There are 2,580 70-m rows, and 3,900 140-m rows in the sample.

2.1.1 *Search Frequency and Timing*

Standardized searches occurred during the fall survey season, which includes the period from August 31 through October 31, 2015. All project components included in standardized searches were surveyed nine times during fall. All searches took place during daylight hours from 06:30 to 17:00.

As specified in the approved Desert Sunlight BBCS, the average search interval for all Project components included in standardized carcass searches during fall was 7.0 days (median 7.0 days). Slight variation in search interval was anticipated due to weather and logistical delays.

Table 2. Area and proportion of solar arrays that are and are not associated with overhead lines at the Desert Sunlight Solar Farm Project, Riverside County, CA.

	Line-associated[1]	Not line-associated	Proportion line-associated
Entire facility	89.4 ha	956.5 ha	0.09
Standardized searches	32.2 ha	291.0 ha	0.10

[1] Line-associated area was estimated as the area of any array that fell within the 30-m strip transect below the MVOH.

2.1.2 *Search Methods*

Standardized carcass searches were performed by BLM-approved biologists, in accordance with methods outlined in the BBCS.

Within the solar field, arrays of solar panels were surveyed by observers traveling on foot. A distance sampling approach was used, whereby biologists slowly walked a transect line along the ends of rows of solar panels in a direction perpendicular to the rows, searching ahead and to the side within the array for bird and bat detections. Biologists scanned out to a maximum perpendicular distance of approximately 70 m from the transect. Biologists carried binoculars to allow them to verify the presence of a detection versus rocks or vegetation. Once a detection was confirmed, the distance of the detection to the transect line was estimated using laser range finders. Each array included in the sample was searched by observers walking two transects – one on the west side and one on the east side of the array with observers looking toward the center of the array.

Once a carcass was detected, it was photographed, and data were recorded according to specifications outlined in section 7.2.5 of the approved Desert Sunlight BBCS. Carcasses were then retrieved from their location on the ground, labeled, and placed in a freezer on site.

Most (74.4%) of the length of fenceline (approximately 10 miles; Figure 2) was searched from a vehicle using the standard protocol. Biologists searched a 6-m wide strip transect centered on the fence from the inner perimeter. Travel speed was below five miles per hour (mph) while searching. Some sections along the fence cannot be driven close to the fence line. The fence line along the western edge of the Project is drivable but the road is approximately 15 m away from the fence and the road and fence are separated by a drainage ditch. The fence along this section is covered with a tan tarp and trees and shrubs have been planted to reduce visibility of the project from the west. Additions of vegetation and the tarp likely reduce potential for bird collision with the fence. This section of the fence was driven to document carcasses, but detections along this portion of the fence are not included in adjusted fatality estimates because detection rates are likely very low. As specified in section 4.2.6 in the approved Desert Sunlight

BBCS, we assume that fatality rates are similar between the portion of fence that was searched and the portion that was not. A separate section of the fence in the southeastern corner of the Project cannot be driven because the eastern edge of the berm that bounded construction ponds is too narrow for a vehicle. Along this portion of the fence, the observer stopped at both north and south ends of the berm and used binoculars to search for carcasses. Finally, the road along a portion of the southwest fence line near the entrance gate is approximately 30 to 50 m from the road and is separated from the fence by an area that has recently undergone vegetation restoration. This area was eliminated from sampling. Fatality rates estimated for sections of the fence that were sampled were adjusted to account for the proportion of fence not sampled with the standard monitoring protocol, as specified in section 4.2.6 of the approved Desert Sunlight BBCS. In other words, the fatality rates (# carcasses/m of fenceline sampled) was multiplied by the total fenceline in the facility to get the total fenceline carcass estimate for the facility.

Comentado [FWS7]: Is there a reason that this can't be done using an estimator based on the fraction that was searched?

Comentado [WEST8]: An area adjustment was applied using exactly the approach you outlined and the Huso estimator was applied. We added a sentence to clarify

The gen-tie line was searched using a 30-m wide strip transect (i.e., 15 m of ground on either side of the overhead line). Sample units along the gen-tie line were chosen by dividing the total length of line from the Project fence south to the Red Bluff Substation just south of I-10 into 1-km segments. Thus, a 47.9% sample of the total length of the line was searched (Figure 3). Biologists slowly walked every other 1-km segment of the line, meandering the width of the strip transect, scanning for dead or injured birds or bats within 15 m (49.2 ft) of the overhead line.

For each detection, a suspected cause of death or injury was assigned based on evidence available from the detection, evidence available on Project infrastructure, and proximity of the detection to Project infrastructure. Detections that had evidence of scavenging and lacked evidence on Project infrastructure were assigned as "unknown" because it cannot be determined whether the event was caused by predation or interaction with project infrastructure. Detections that were intact (i.e., no evidence of scavenging) and located in close proximity to Project infrastructure (e.g., found directly beneath overhead lines) had a suspected cause of death attributed to the respective Project component. However, it should be noted that there is substantial uncertainty associated with cause of death assignments because no events were directly observed. Detections assigned to the "unknown" category were included in fatality estimates if they were located within standardized carcass search areas, and all detections made during the fall season are reported here.

2.2 Carcass Persistence Trials

Carcass persistence trials were conducted throughout the fall period. Carcasses from three size classes (small [0-100 g], medium [101-999], and large [1000+ g]) were used for trials. The small size class comprised house sparrows (*Passer domesticus*) and 2-3 week old coturnix quail (*Coturnix coturnix*), the medium size class comprised rock pigeons (*Columba livia*), chukar (*Alectoris chukar*), and adult coturnix quail, and the large size class comprised hen mallard (*Anas platyrhynchos*) and hen ring-necked pheasant (*Phasianus colchicus*).

2.2.1 *Carcass Persistence Data Collection*

To quantify carcass persistence rates, 15 small, 10 medium, and 5 large carcasses were randomly placed and monitored along the gen-tie line during fall 2015. Within the solar arrays the same numbers of each size category were placed, for a total of 60 carcass persistence trials at Desert Sunlight during the fall season, as specified in the approved Desert Sunlight BBCS. By placing carcasses inside (within arrays and along inner perimeter of the fence) and outside (along the gen-tie) the project fence, the possibility that there are different carcass persistence rates inside and outside the project fence is accounted for. Fifteen carcasses within the Project fence (within solar arrays and along the fence) were monitored using motion-triggered digital trail cameras, while the remaining carcasses were visited on foot, for 30 days or until the carcass had deteriorated to a condition at which it would no longer qualify as a documentable fatality. No carcasses along the gen-tie line were monitored with cameras because of theft and vandalism concerns. Carcasses without trail cameras were visited and photographed once per day for the first four days, and then every three to five days until the end of the monitoring period. To avoid training scavengers to recognize cameras as "feeding stations", trail cameras were installed five days before specimens were placed, and two fake cameras without bias trial carcasses were also placed within the Project fence and periodically moved to new locations within the fence. Periodic ground-based checking of carcasses with trail cameras also occurred to guard against misleading indicators of carcass removal, such as wind blowing the carcass out of the camera's field of view. To minimize potential bias caused by scavenger swamping (Smallwood 2007, Smallwood et al. 2010), carcass-persistence specimens were distributed across the entire Project, not just in areas subject to standard searches, and trials were initiated in smaller numbers on two different dates throughout the fall season.

2.2.2 *Estimating Carcass Persistence Times*

Measurements of carcass persistence rates were subject to censoring. In this context, censoring refers to the instance when a value (e.g. days a carcass is present before being removed) may not be known exactly, but is known to be within a finite range. For example, suppose a carcass was checked on day 7 and was present, and was checked again on day 10, but was found to be missing. The exact time until removal is unknown; however, it is known that the carcass became unavailable at some point between 7 and 10 days. This carcass would be considered "interval censored". Similarly, if a carcass lasts the entire 30-day trial period, that carcass is "right censored"— it is known that the carcass lasted at least 30 days, but it may have persisted longer. Because carcass persistence data were censored, persistence was analyzed using methods that can accommodate censored data and still produce unbiased estimates of the probability of persistence (Therneau 2015, Therneau and Grambsch 2000). It is beyond the scope of this document to provide statistical foundations of censored-data survival models but functions identical to those provided with the USGS-developed fatality estimator software (Huso et al 2012) were used to fit survival models to the censored carcass persistence data, and some background is available in the documentation provided with that software.

USGS-developed fatality estimator software (Huso et al 2012) was used to fit survival models to the censored carcass persistence data. The USGS software used to estimate carcass

Comentado [FWS9]: By placing carcasses in unsearched areas, doesn't this introduce an unnecessary assumption that carcass persistence is the same in searched and unsearched areas? Have you tested that carcass persistence is the same in searched and unsearched areas?

Comentado [FWS10]: This isn't clear. Is it possible to only distribute carcasses on two dates and have small numbers? Is it possible to distribute the carcass on more dates, so there are fewer "arriving" at any one time?

Comentado [WEST11]: If we restrict trials to searched areas we risk scavenger swamping. If we use the entire facility we need to assume searched areas are similar to unsearched areas. Given that the searched sample was randomly drawn, it is unlikely to have an intrinsically higher removal rate, In addition, the habitats are similar for both the searched and unsearched areas.

With respect to two vs. more trial dates, the addition of 15 carcasses across 5 square miles of solar field (assuming we use unsearched areas) amounts to one carcass per 200 acres and probablynot enough to appreciably affect the scavenging pool. Placing carcasses on more dates becomes very labor intensive as well and can complicate check schedules.

persistence calculates the period over which there is less than a 1% chance for a carcass to persist. The 'effective search interval' is defined as the shorter of a) the length of time beyond which there is less than a 1% probability that a carcass persists, and b) the actual search interval (Huso 2010). The probability of persistence is given for the effective search interval, and the probability that a carcass persists through the actual search interval is equal to *p* (persist through effective search interval) * effective search interval / actual search interval.

There were four distributions implemented in survival models used to estimate the probability a carcass is unscavenged and available to be found at the end of the search interval (*r*): exponential, Weibull, loglogistic, and lognormal. These four distributions exhibit varying degrees of flexibility in order to model a wide variety of distributions of persistence time. Akaike's Information Criterion adjusted for sample size (AICc; Akaike 1973) was used to rank the fit of each survival model with combinations of the covariates carcass size, Project component, season, and visibility, to observed carcass persistence data.

2.3 Searcher Efficiency Trials

Searcher efficiency trials were conducted throughout the fall period. Carcasses from three size classes (small, medium, and large) were used for trials. The small size class comprised house sparrows and 2-3 week old coturnix quail, the medium size class comprised rock pigeons, chukar, and older coturnix quail, and the large size class comprised hen mallards and hen ring-necked pheasants.

2.3.1 *Searcher Efficiency Data Collection*

Training of biologists on the Project-specific protocol and early assessments of habitat conditions within the solar arrays suggested that the amount of cobble present in the soil may be an important factor influencing searcher efficiency. To satisfy requirements regarding consideration of visibility class per the BBCS and address the influence of cobble cover on searcher efficiency, sample units in the solar arrays and along the gen-tie were stratified by cobble cover and assigned to one of two classes (<15% and >15% cobble cover). Classes were determined by making ocular estimates of cobble cover at each sample unit and then evaluating the frequency histogram of sample units across the range of estimated cobble cover (Figure 4). A natural break point was identified at 15% cobble cover, so the same value was chosen as the break point that defined the two cobble cover classes. Thus, in the solar arrays, two sets of searcher efficiency trials were conducted (one set in each cobble cover class; ~~total~~ *n* in low cobble = ~~45~~ 30 small birds, 21~~30~~ medium birds, and 9~~15~~ large birds; *n* in high cobble = 15 small birds, 9 medium birds and 6 large birds, most of which are in excess of that ~~as~~ agreed upon in section 7.4 of the approved Desert Sunlight BBCS). Along the gen-tie, visibility was expected to be related to vegetation and rock cover. Thus, searcher efficiency trials along the gen-tie occurred in two visibility classes (*n* for each class = 15 small birds, 10 medium birds, and 5 large birds (easy: ≥90% bare ground, vegetation <6" tall; and more difficult: <90% bare ground, vegetation ≥6" tall). Thirty searcher efficiency trials (*n* = 15 small birds, 10 medium birds, and 5 large birds) occurred along the fence in the only visibility class present on the fence (easy visibility). During fall, a total of 180 searcher efficiency trials occurred at the Project. Locations

Comentado [FWS12]: This isn't very clear. two sets of trials should be n= 30 (s); 20 (m); 10 (l). Trial carcasses of 45, 30, 15 sounds like a multiple of three. Please clarify.

Comentado [WEST13]: We clarified

Con formato: Fuente: Sin Cursiva

Con formato: Fuente: Cursiva

for trials were chosen by taking a randomized sample of all locations included in standardized carcass searches.

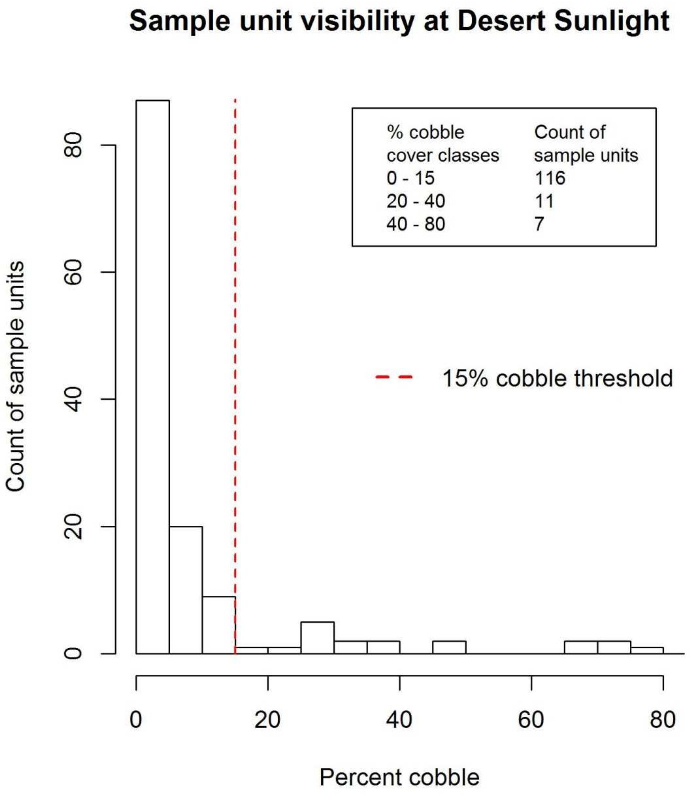

Figure 4. Frequency histogram of sample units (in the arrays only) at Desert Sunlight Solar Farm Project by estimates of cobble cover. Based on this distribution, each sample unit was assigned to one of two classes of cobble cover (<15%; >15%).

2.3.2 *Estimating Searcher Efficiency*

Searcher efficiency at Desert Sunlight was estimated separately for linear features (the project fence and the gen-tie line), and the solar arrays, reflecting the different search methods used on arrays and linear features. For linear features, logistic regression models were fit to searcher efficiency data and AICc was used to compare models. Models including effects of carcass size (three classes), visibility (two classes; gen-tie only), and season were compared to each other and the null model. Model selection indicated that the most supported model included main effects of Project component, carcass size, and season and an interaction between season and component. Once the analysis was focused on fall data only (because of the seasonal effect), the most supported model was reduced to main effects of Project component and carcass size. Once the most supported model was chosen and appropriate classes identified, searcher efficiency, or the proportion of carcasses detected, *p*, was calculated for each class using the following equation:

$$p = \frac{Number\ of\ Carcasses\ Observed}{Number\ of\ Carcasses\ Available}$$

The data for this analysis included all searcher efficiency trial carcasses from the fall 2015 season.

For the solar arrays, searcher efficiency was evaluated using a distance sampling approach (Buckland et al. 1993). Distance sampling assumes perfect detection on the transect line (at distance = 0), an assumption that is likely valid in the solar arrays given the relatively flat & vegetation-free nature of the soil surface. A curve is fitted to the observed carcass data that predicts probability of detection as a function of distance from the transect line. The mean value of this function over a specified distance, *w,* is equal to the average searcher efficiency for a transect of width *w*. The mean value of the detection curve is the integral of the detection function calculated between 0-m and the maximum survey distance (*w;* half the width of the solar array row), divided by the maximum survey distance:

$$p = \frac{\int_0^w f(x)dx}{w},$$

where f(x) is the detection function evaluated at distance, *x*.

One departure in the methods used here, relative to the methods presented in Buckland et al. (1993), was that for this study the detection function was estimated using trial carcasses, which meant that there were both presence (detected) and absence (not detected) data available to fit the detection function (Figure 5). The availability of both presence and absence data means that the detection function can be estimated using only trial carcasses whose distribution is known. Therefore the detection function, the average searcher efficiency among the arrays, and the final fatality estimate within the arrays are all insensitive to the spatial distribution of carcasses within individual arrays, and the overall searcher efficiency estimate is valid even if the distribution of carcasses among the arrays is not uniform.

Distances of trial carcasses (trials both found and missed) from the transect line were used to fit half-normal, exponential, and hazard rate distribution detection functions for searches among the arrays, which are all commonly used functions for distance sampling surveys (Buckland et al. 1993). The fit of detection functions were compared using AICc and each model was fit with covariates (season, carcass size, cobble cover class), and without. The most supported detection function had an exponential distribution and the most supported among these models included an interactive effect of carcass size and season.

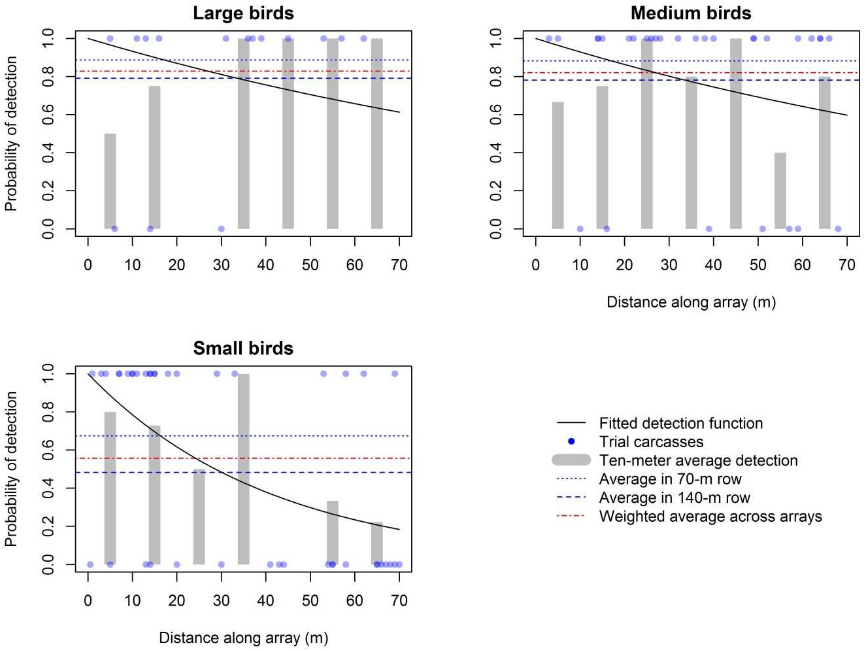

Figure 5. Estimated detection probabilities for bird carcasses by size class during fall (August 31 – October 31) 2015 at the Desert Sunlight Solar Farm Project, Riverside County, California. Distance sampling was used when searching solar arrays only. Average probability of detection over 70-m (arrays relying on a 35-m viewshed) and 140-m (arrays relying on a 70-m viewshed) panel rows in solar arrays are presented. Estimates are informed by 45, 30 and 15 small, medium and large bird trials respectively.

Comentado [FWS14]: Please include n for each figure.

Comentado [WEST15]: We added n

Because the solar arrays were surveyed by searchers who walked down both sides of the rows of panels, the width of the search transect was specified as half the width of the rows of panels. For larger birds, there is almost certainly a non-zero detection probability beyond this distance but the bias that occurs by ignoring this non-zero detection probability is conservative (i.e. the searcher efficiency is underestimated). Some solar arrays have row widths of 70 m (search transect width of 35 m) and some have row widths of 140 m (search transect width of 70 m). The weighted average searcher efficiency is calculated based on the number of panel rows of each length in the survey sample:

$$p_{weighted\ average} = \frac{n_{70}}{n} \times \frac{\int_0^{35} f(x)dx}{35} + \frac{n_{140}}{n} \times \frac{\int_0^{70} f(x)dx}{70},$$

where n_{70} is the number of 70-m rows in the sample, n_{140} is the number of 140-m rows in the sample, and *n* is the total number of rows in the sample. Searcher efficiency was higher for the arrays with a width of 70 m, and overall searcher efficiency was estimated as a weighted average based on the proportions of 70-m arrays and 140-m arrays in the sample units.

2.4 Fatality Estimator

Fatality rate estimation is a complex task due to several variables inherent to every fatality monitoring study. Carcasses may persist for variable amounts of time due to local scavenger activity or environmental conditions leading to carcass degradation over time. Carcasses and feather spots are also detected with varying levels of success based on carcass characteristics and ground cover (e.g., vegetated areas underneath the gen-tie line versus cleared areas beneath solar panels). For these reasons, it is generally inappropriate to draw conclusions based on the raw number of fatalities alone. The desire to estimate fatalities given these variables has driven the development of several statistical methods for estimating fatalities (e.g., Smallwood 2007, Huso 2010, Korner-Nievergelt 2011). All of these fatality estimation methods share a similar underlying model. Generally, the fatality estimation for a given site may be written as:

$$F=C/rp,$$

where *F* is the total number of fatalities, *C* is the number fatalities detected and included in fatality estimation*, r* is the probability a carcass is unscavenged and available to be found at the end of the search interval, and *p* is the probability of detecting a carcass (Huso 2010). Huso (2010) describes the use of a binomial model to estimate the probability of carcass detection; in the present study, the binomial carcass detection model was used to calculate fatalities at project linear features (fence, overhead lines), and the weighted average probability of detection based on distance sampling (described above) was used to estimate probability of detection within the solar arrays.

.

All fatality estimates were calculated using the Huso estimator estimator (modified to accommodate the distance-sampling based estimate of searcher efficiency in the solar arrays), as well as 90% confidence using bootstrapping (Manly 1997). Bootstrapping is a computer simulation technique that is useful for calculating point estimates, variances, and confidence intervals for complicated test statistics. A total of 1,000 bootstrap replicates was used for each variable including of searcher efficiency (*p*), probability of a carcass persisting to the next search ($\hat{r}$), adjusted search interval and observed fatalities. From these bootstrap samples, the probability of available and detected was calculated and applied to the bootstrapped observed fatalities. The lower 5th and upper 95th percentiles of the 1,000 bootstrap estimates provide estimates of the lower limit and upper limit of an approximate 90% confidence interval on all estimates.

2.5 Incidental Reporting

Some detections were outside standardized search areas, or were within search areas but not observed during standardized searches. Such detections were found by WEST avian biologists and operational personnel and were considered “incidental” detections. When found by operational personnel, these detections were reported to WEST avian biologists for documentation. Data on incidental detections are reported here, as well as in the Desert Sunlight SPUT Avian Injury and Mortality Report Forms August - October 2015. All detections made in search areas during the reporting period were included in fatality estimates, regardless of whether they were detected incidentally or during searches.

3.0 MONITORING RESULTS

3.1 Summary of Avian Detections

During fall 2015, a total of 83 avian detections (including incidentals) of 38 identified species were recorded (Table 3). The most common identified species was American coot (*Fulica americana*) with 11 detections. Most detections (n = 54, or 65.1% of total detections) occurred in the solar arrays (Figures 2 and 3; Tables 4, 5, and 6). Sixty-two (74.7%) detections occurred during standardized carcass searches and 21 (25.3%) were documented as incidentals. No bats were detected during the fall season. For fresh carcasses, body weights and weather conditions the preceding nights are described in Appendix B.

Table 3. Number of individual bird detections, by species, found during scheduled searches and incidentally (August 31 – October 31, 2015) ~~2015~~ at the Desert Sunlight Solar Farm Project, Riverside County, California. LA = line-associated; NLA = non-line associated.

[1] Ring-necked pheasants are used for bias trials and these two detections were likely from trial carcasses; however, ring-necked pheasants have been reported in Riverside County, CA south of the Project area near the Salton Sea (eBird 2015). Thus, we cannot be certain that these detections were exclusively from trial carcasses.

[2] See literature cited for migration behavior references; information for most species was taken from the respective species accounts found in Birds of North America (BNA) Online (http://bna.birds.cornell.edu/bna/); where information on migration behavior was lacking in BNA accounts, Newton (2008) or Murray (2004) were used.

Non-line associated	6	0	1	38	54.2
Percent of Total	**20.5**	**1.2**	**1.2**	**77.1**	**100.0**

* Suspected cause of death was assigned based on evidence available on the detection, evidence available on Project infrastructure, and proximity of detection to Project infrastructure. Detections that had evidence of scavenging and lacked evidence on Project infrastructure were assigned as "unknown" because it can't be determined whether the event was caused by predation or interaction with project infrastructure. Detections that were intact (i.e., no evidence of scavenging) and located in close proximity to Project infrastructure (e.g., found directly beneath overhead lines) had a suspected cause of death attributed to the respective Project component. However, there is substantial uncertainy associated with cause of death assignments because no events were directly observed.

3.2 Temporal Patterns of Avian Detections

The number of detections recorded daily during the reporting period ranged from zero to six, and were more or less evenly distributed throughout the season (Figure 6). Daily detections peaked on September 22 and this event was reported to the agencies per Special Purpose Utilities Permit Condition H(c). The number of detections per day represents those discovered during standardized carcass searches and incidentally.

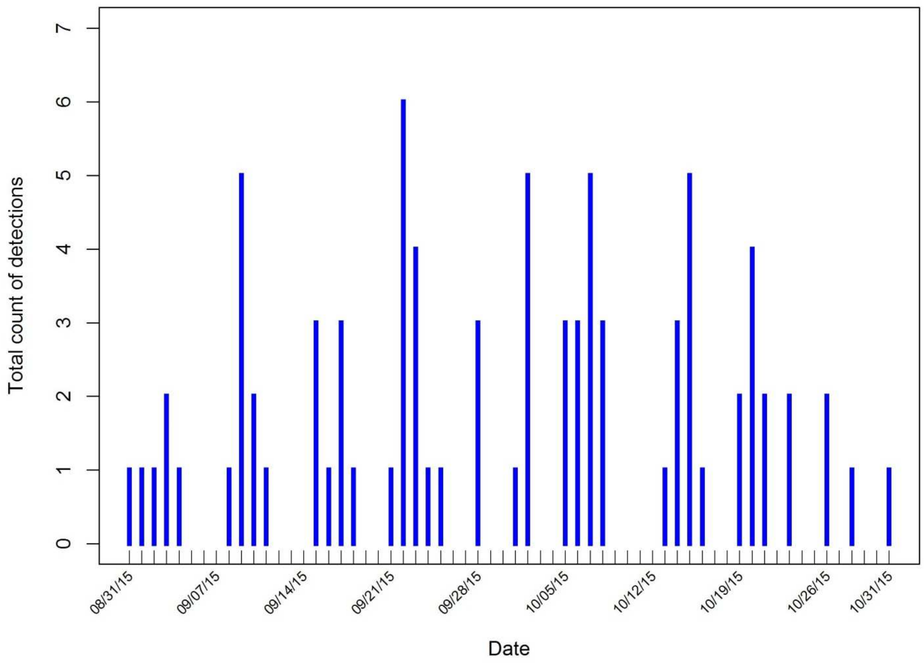

Figure 6. Total count of detections (including incidentals) by date during fall (August 31 – October 31) 2015 at the Desert Sunlight Solar Farm Project, Riverside County, California.

3.3 Spatial Distribution of Avian Detections

3.3.1 *Detections by Project Component*

During the reporting period, detections were documented from the solar arrays, the Visitor Center, and the gen-tie line; no detections occurred ~~at the Visitor center or~~ along the fence (Tables 3, 4, and 5). Of the 54 detections within the solar arrays, 16.7% (9) were associated either with overhead lines or arrays that co-occurred with overhead lines. Twenty-eight detections (33.7% of season total) were along the gen-tie line, and one detection (1.2% of season total) was at the Visitor Center.

3.3.2 *Feather Spot Detections*

Fourteen (16.9%) of the 83 detections made during fall consisted only of feather spots. Along the gen-tie, nine of 28 detections (32.1%) were feather spots. Five of 54 detections (9.3%) in the solar arrays were feather spots. There were no detections along the fence during fall.

3.4 Detections of Injured or Stranded Birds

There were six injured or stranded birds detected during fall 2015. Three injured birds were detected at line-associated (ruddy duck [*Oxyura jamaicensis*]) and non-line associated arrays (2; mourning dove [*Zenaida macroura*] and western grebe [*Aechmophorus occidentalis*]). Three stranded but uninjured birds were detected at line-associated (common loon [*Gavia immer*]) and non-line associated (ruddy duck and eared grebe [*Podiceps nigricollis*]) arrays. The injured mourning dove and ruddy duck were transported to wildlife rehabilitation facilities; the ruddy duck was released by the rehabilitator on the same day. The injured western grebe died before it got to a rehabilitation facility. The stranded ruddy duck, eared grebe, and common loon were evaluated for a short period for injuries and general stress and when none were observed, released at Lake Tamarisk. Three detections of injured or stranded birds were included in fall fatality estimates; three were excluded because they were found outside of a standardized carcass search area.

3.5 Summary of Bat Detections

No bats were detected during the fall 2015 season.

3.6 Carcass Persistence Trials

Data from carcass persistence trials were available from late winter, spring, summer, and fall at the solar field and gen-tie line (n = 215 total). Based on carcass persistence data from all seasons so far in 2015, survival models were compared for relative quality using the corrected AICc score, as suggested in Huso (2010). The AICc score provides a relative measure of model fit and parsimony among a selection of candidate models, and provides a framework for testing hypotheses regarding which factors contribute to carcass persistence rates. Carcass size was tested as a potentially important variable, as larger carcasses tend to persist longer and may be more likely to leave feather spots which persist for long durations, whereas smaller carcasses may be more likely to be completely removed. Project component (solar arrays, gen-tie line) was also included as a potentially important variable, as was season.

The model with lowest AICc score is typically chosen as the “most supported” model relative to other models tested; however, any model within two AICc points of the most supported model is considered competitive with the most supported model (Burnham and Anderson 2004). Preliminary modeling suggested a main effect of season, so further modeling efforts were restricted to data collected in fall only. The most supported model using only the fall data included main effects of carcass size and Project component, with a removal time that was lognormally-distributed (Appendix C). Estimates of carcass removal time and persistence probabilities from the most supported model are reported in Table 6, and estimates of proportion of carcasses remaining as a function of days since carcass placement are provided in Figure 7. Detailed estimates of carcass removal and associated confidence intervals are provided in Appendix C.

Table 6. Mean and median carcass removal time and probability of a carcass persisting through the effective search interval during the fall (August 31 – October 31) 2015 season at the Desert Sunlight Solar Farm Project, Riverside County, California.

Carcass size	Project component	Mean removal time (days)	Median removal time (days)	Day when 50% carcasses were removed	Probability of persistence
Small	Arrays/fence	2.2	1.5	1 - 2	0.46
	Overhead		0.5	<1	
Small	lines	0.1			0.08
Medium	Arrays/fence	17.4	16	8	0.80
	Overhead		1.5	1 – 2	
Medium	lines	0.8			0.30
Large	Arrays/fence	203.3	>30	Na	0.98
	Overhead		3.5	3 - 4	
Large	lines	9.7			0.72

Comentado [FWS20]: Also include the Time until 50% of the carcasses have been removed.

Comentado [WEST21]: median removal time is the time until 50% of carcasses are removed.

Comentado [WEST22]: First day that 50% are gone is day 8, nothing changes the rest of the trial. The rest (5 out of 10) are censored.

Right censored events skew the median metric.

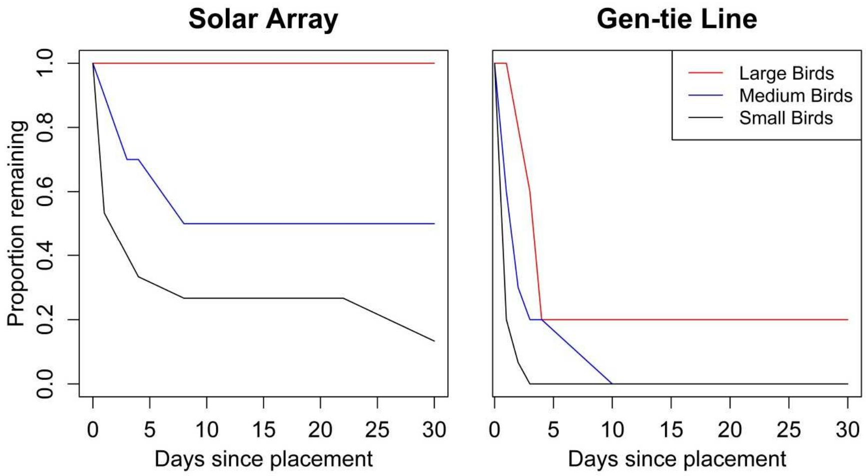

Figure 7. Proportion of trial carcasses remaining as a function of days since placement and carcass size class (n = 30, 20, and 10 for small, medium, and large size classes, respectively) during the fall (August 31 – October 31) 2015 season at the Desert Sunlight Solar Farm Project, Riverside County, California.

3.7 Searcher Efficiency Trials

During the reporting period, a total of 180 searcher efficiency trials were placed at the Project. Most trials were available to be found, but some disappeared before or during the trial. Overall, 90 trials were placed in the solar arrays and 87 were available to be found; 30 trials were placed along the perimeter fence (inner perimeter only) and 29 were available to be found; and 60 trials were placed along the gen-tie line and 51 were available to be found. Three observers conducted searches at the Project during fall. Searcher efficiency trials were conducted on each observer in approximate proportion to the number of searches they conducted at the Project, as follows: Sarah Nichols (number of trials available to be found: 28), Darin Blood (62), and Wanda Bruhns (77). All trials were included in estimation of searcher efficiency.

In the solar arrays, the model that included an effect of carcass size was chosen as the most supported model to estimate searcher efficiency (Appendix C). Within the solar arrays, searcher efficiency was: 55.7% for small birds, 82.1% for medium birds, and 82.9% for large birds (Figure 5; Appendix C).

For linear Project components, the model that included an effect of carcass size, Project component, and season was chosen as the most supported model to estimate searcher efficiency. Along the fence, searcher efficiency was 90.1% (CI: 78.1 – 100%), 94.9% (CI: 86.2 – 100%), and 98.0% (CI: 92.6 – 100%) for small, medium, and large carcasses, respectively. Along the gen-tie, searcher efficiency was 44.7% (CI: 27.4 – 62.4%), 62.5% (CI: 45.5 – 80.0%), 81.0% (CI: 60.0 – 100%) for small, medium, and large carcasses, respectively. Detailed estimates of searcher efficiency estimates specific to each component and carcass size are reported in Appendix C.

3.8 Fatality Estimates

Fatality estimates were calculated separately for each component (solar arrays, fence, and overhead lines). Ultimately, 22 detections were excluded from the fatality analysis because they were found outside standardized search areas (Table ~~4~~7; Appendix C). All 83 detections that occurred~~made~~ during fall are reported in Table 3.

Table 7. Status of detections during the fall (August 31 – October 31) 2015 season at the Desert Sunlight Solar Farm Project, Riverside County, California. All detections outside the search area were excluded from the fatality analysis, regardless of whether they occurred during a standardized carcass search or incidentally.

	Carcass search	Incidental detection	*Pushed to next season's fatality estimate	*Pulled from previous season's fatality estimate
Inside search area	55	6	0	0
Outside search area	7	15	0	0

* Incidental detections occurring after the last standardized carcass search in a season are considered for inclusion in the fatality analysis for the following season. This is consistent with the assumption we make throughout the monitoring seasons; that carcasses found incidentally would have been available to be found on the next scheduled search. This assumption may result in some carcasses found during one season but considered in the following season's fatality analysis. Once a carcass has been moved to a different season's analysis it is still subject to the same criteria for inclusion or exclusion based on location (in versus out of a searched area) and carcass age (greater than versus less than the search interval).

During fall 2015, 296 carcasses (90% CI: 198 – 461) were estimated for the solar arrays. There were an estimated 0.115 carcasses per acre (within the solar field only; 296 estimated carcasses/2,585 acres) and an estimated 0.538 carcasses per nameplate MW (296 estimated carcasses/550 MW) within the solar field.

Estimates of fatalities along the gen-tie are heavily influenced by the high rates of scavenging observed during the limited trials at the gen-tie (i.e., large correction factors) and are likely very unreliable. The estimate along the gen-tie was 894 carcasses (90% CI: 362 – 2,948). No carcasses were estimated for the perimeter fenceline because there were no detections made along the fence. A complete list of estimates for each Project component and carcass size class with confidence intervals is presented in Appendix C.

4.0 DISCUSSION

The 2015 fall season represented the third full season of standardized monitoring at Desert Sunlight per the BBCS. Searcher efficiency and carcass persistence trials were conducted concurrently at the solar arrays, fencelines, and along the gen-tie line. Data from these trials were used to produce fatality estimates adjusted for searcher efficiency and carcass persistence bias. Although these estimates were produced from a statistically robust sample, only limited inference may be drawn from three seasons of data. These results should be considered preliminary because estimating carcass persistence, searcher efficiency, and adjusted numbers of fatalities within each season represents information based on a limited sample size. As more data are collected throughout the monitoring year (and additional quality assurance/quality control measures occur, for example characterizing feather spots to species or size class), data from all seasons may be pooled. At that time, data will be tested for seasonal differences retrospectively, but because seasonal estimates will be produced from the much larger annual data set, they may differ from what is reported here because they are based on a larger, more informative sample.

4.1 Carcass Persistence and Searcher Efficiency Trials

The degree to which carcasses persist on the landscape depends on a variety of factors reflecting seasonal and inter-annual variation in habitat, climate, and the scavenger community. The composition and activity patterns of the scavenger community often vary seasonally as birds migrate, new juvenile birds and mammals join the local population, and mammalian scavengers variably hibernate or estivate. The scavenger community may also vary substantially from year to year because of variation in annual reproduction and survival related to changes in landscape condition. Climatic conditions that vary seasonally and annually also may contribute to variation in carcass decay and removal rates due to variation in temperatures, solar insolation, wind patterns, and the frequency of flooding events. Thus, rates of carcass persistence reported here should be interpreted cautiously as they may change over the coming months.

Fatality estimates are influenced by the relationship between carcass removal dynamics and search intervals. In practical terms, longer search intervals reduce average probability that a carcass persists until the next search. In terms of the analysis, this can manifest as a lower probability of persistence through the effective search interval, or an effective search interval that is shorter than the nominal search interval. In either case, the adjustment to carcass counts due to carcass removal dynamics is calculated as

$$\frac{length\ of\ effective\ search\ interval}{length\ of\ nominal\ search\ interval * average\ probability\ of\ persistence\ through\ the\ effective\ search\ interval}$$

The adjustment to estimated fatality for carcass removal increases with longer search intervals, and the variance in the estimate may increase, also.

Carcass persistence at the Project is clearly influenced by whether a carcass is located in the solar field (inside the perimeter fence) or along the gen-tie (outside the perimeter fence), with higher removal rates occurring along the gen-tie. Although the same scavenger species may occur at both Project components, a difference in scavenger density or activity between the components could possibly be responsible for the different rates of carcass persistence. If there are differences in scavenging rates between the trial carcasses and naturally-occurring carcasses, it is possible that the high scavenging rates observed along the gen-tie have resulted in inflated fatality estimates. This hypothesis may be evaluated in the annual report by comparing persistence rates of trial carcasses to the age of carcasses detected by observers. Given the very high scavenging rates along the gen-tie line, fatality estimates for the gen-tie are unreliable.

Searcher efficiency was influenced by Project component, carcass size, and season. In the solar arrays, searcher efficiency was high (>0.5) for all carcass size classes and this is likely influenced by the limited vegetation cover beneath solar panels. Beneath the gen-tie line, vegetation cover is higher in some portions of the strip transects, but results reported here support the hypothesis that visibility class was not a factor in searcher efficiency along the gen-tie line during fall. Placement of trial carcasses in both difficult and easy visibility classes ensures that the adjustment due to searcher efficiency accounts for both visibility classes, even if there is a real difference in searcher efficiency that cannot be detected with the trial data.

4.2 Distribution of Fatalities and Fatality Estimates

Detections were distributed throughout the fall season, and there were no clear peaks in detections associated with a particular date or range of dates. Tapering of daily detections at the beginning and end of the fall season (Figure 6) suggests that the current dates that define the season likely capture the majority of fall migration at the Project.

Most (65.1%) of the 83 detections made during fall were in the solar field. Approximately 13% of the carcasses found in search plots had overhead lines associated with those plots and 10% of the plots searched had lines associated with them, suggesting overhead lines within the solar field may not influence mortality. The absence of any detections along the fence in fall coupled with the very low number of detections in previous seasons (spring: 2; summer: 1) and relatively high carcass persistence rates inside the fence suggest the perimeter fence at the Project may not be an important source of mortality.

Composition of detections during fall 2015 included 13 avian guilds. Waterbirds and waterfowl comprised the majority of detections (n = 21), followed by rails and coots (n = 13), grassland birds and sparrows (n = 12), and warblers (n = 10). All other guilds were represented by fewer than ten detections. No bats have been detected since monitoring began at the Project. Species that migrate nocturnally were detected most frequently during fall (n = 21 species). Ring-necked pheasants were included in the list of detected birds (Table 3), but these detections were most likely from trial carcasses. However, because ring-necked pheasant have been reported in

Riverside County, CA (eBird 2015) south of the Project area near the Salton Sea, we could not be certain that both detections were from trial carcasses.

Detections attributed to an unknown cause accounted for 77.1% of all detections during the reporting period, and most of those attributed to an unknown cause were found in the solar arrays. Of the 54 detections made in the solar arrays, 11.1% were feather spots. Determining a cause of mortality from a feather spot is challenging because there is rarely visible evidence available on which to determine a cause of death. Thus, feather spots with an unknown cause of mortality could be encountered anywhere birds occur, and an unknown cause of a sizeable proportion of the carcasses is not unique to the Project. Further, the relatively large proportion of feather spots (18.1%) among the detections for the Project as a whole may inflate the fatality estimate based on the potential for multiple feather spots resulting from one fatality, feather spots resulting from predation not associated with the facility, or other causes.

Facility	860	348 - 2830	203	112 – 331	30	11 - 54	*96*	16 - 294

Comentado [FWS23]: These percentages are different than they were in the Summer report (75% and 30%). Please explain the difference.

Comentado [WEST24]: For the summer report we made an estimate of easy and difficult visibiltity based on our searchers' impression of the site. By the time we produced the fall report we had been able to put together a better estimate of proportion in each visibility class.

Con formato: Fuente: Negrita

Table C-2. Carcasses excluded from the fall 2015 fatality analysis at the Desert Sunlight Solar Farm due to 1) having been detected outside of a regular search area or 2) having an estimated carcass age that is greater than the actual search interval and hence violating assumptions of the Huso estimator.

Parameter	Small birds	Medium birds	Large birds	Unknown size	Bats

Desert Sunlight Solar Project

Avian and Bat Monitoring

WEST Inc.

Environmental
& Statistical
Consultants

Technical Advisory Group Meeting

January 20, 2016

Monitoring Objectives

- Estimate overall annual avian fatality rate and species composition associated with the Project infrastructure. This estimate will include mortality associated with solar arrays, overhead lines including the gen-tie line, perimeter fence and other features of the Project that may result in injury and fatality.
- Determine whether there are spatial and temporal/seasonal patterns of mortality associated with project infrastructure (e.g., different fatality rates near panels on the edge of the arrays vs. the interior area of the arrays).
- Provide information that will assist the BLM in consultation with the USFWS in understanding which species and potentially which regional populations are at risk.
- Collect data in such a way that the BLM in consultation with the USFWS may make comparisons with other solar sites.

Preliminary/Interim Results

- This is a quarterly report, and we consider the estimates preliminary; they may change because of the statistical methods used and potential adjustments.
  - Potential pooling of information across seasons to get better estimates
  - Additional QA/QC conducted in the annual report
  - TAG recommendations may alter definitions (e.g. unknown classifications, etc).

Reporting Period

August 31– October 31, 2015

1. Standardized carcass searches
   - 7-day intervals
2. Incidental carcass finds
3. Carcass persistence trials
4. Searcher efficiency trials
5. Preliminary fatality estimates

All surveys conducted by BLM-approved WEST biologists

Percent of Facility Searched

Project Component	Total Size	Units	Percent of Component Searched
Solar arrays	447	Solar arrays	29.5[1]
Fence	16.7	Kilometers	99.4[2]
Generation tie line	19.2	Kilometers	47.9[3]

[1] Percent area that was searched in summer 2015. Slightly less than 30% total because of unequally-sized arrays.

[2] 74.4% of the fence is fully accessible and surveyed following the standard protocol, while approximately 25% of the fence is surveyed from a distance. Fatality rates estimated for sections of the fence that are sampled were extrapolated to sections of the fence where the standard monitoring protocol cannot be used, as described in section 4.2.6 of the approved Desert Sunlight BBCS. A very short segment near the gate is not sampled due to restoration activities.

[3] 52.1% of gen-tie will be sampled in 2016.

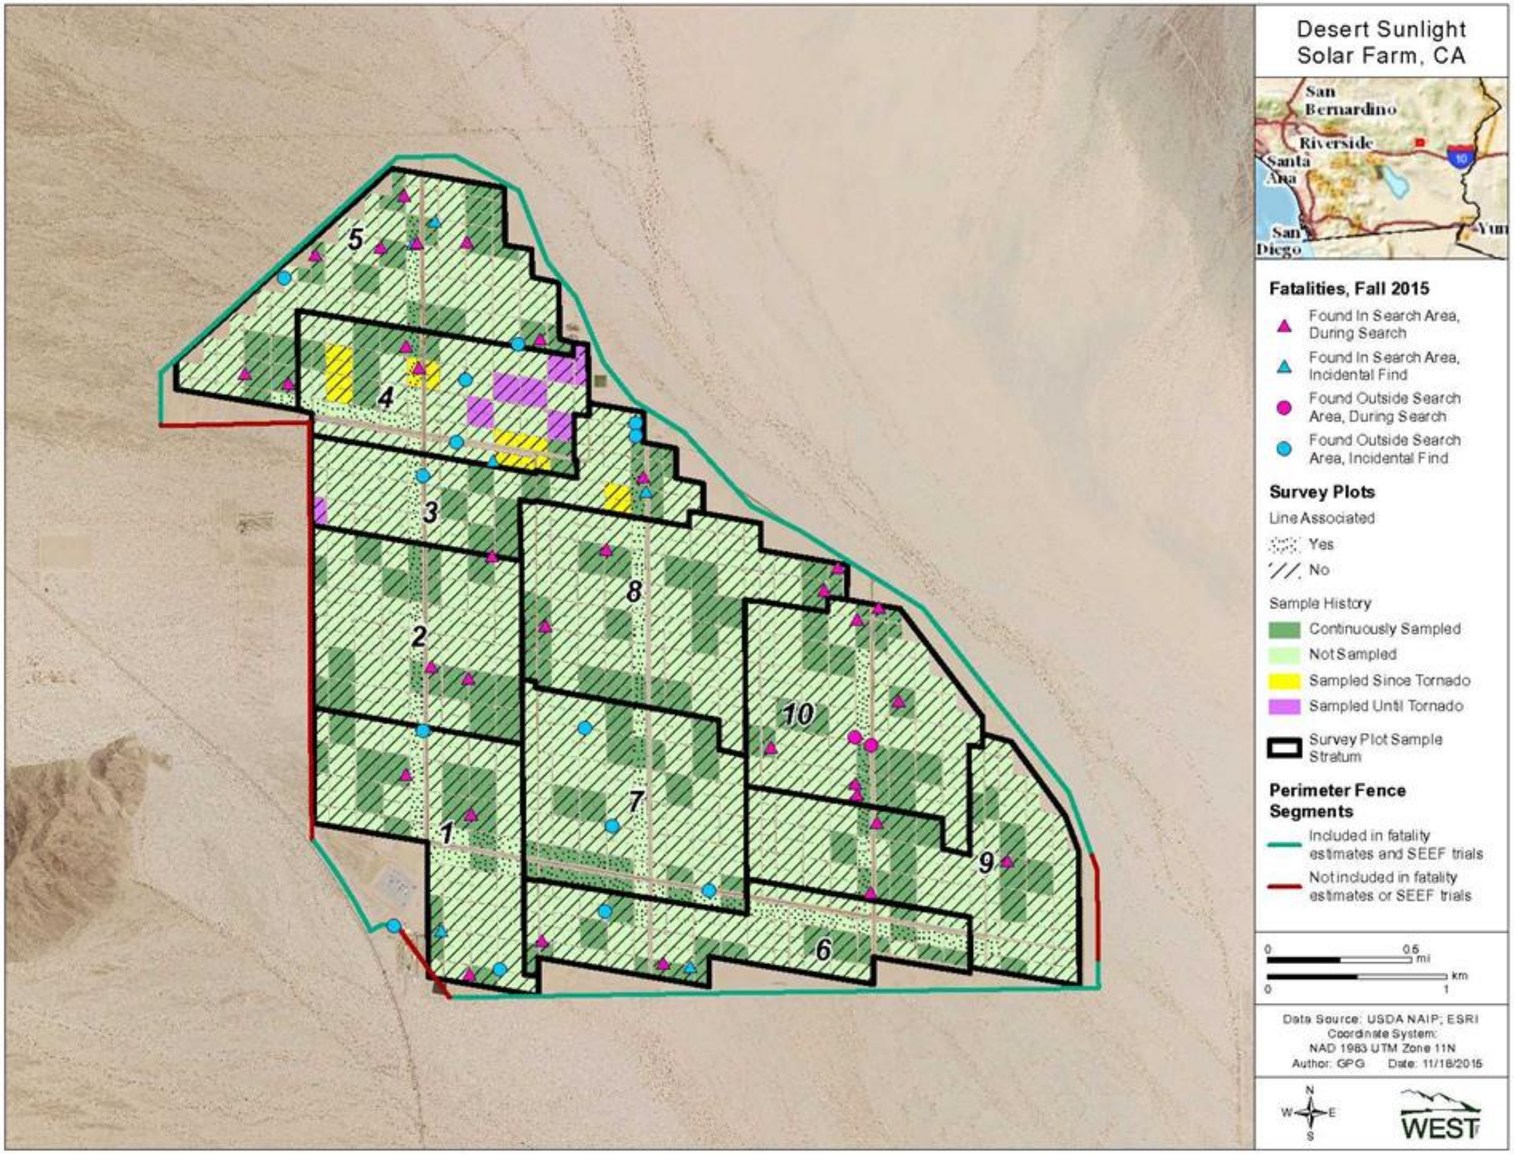
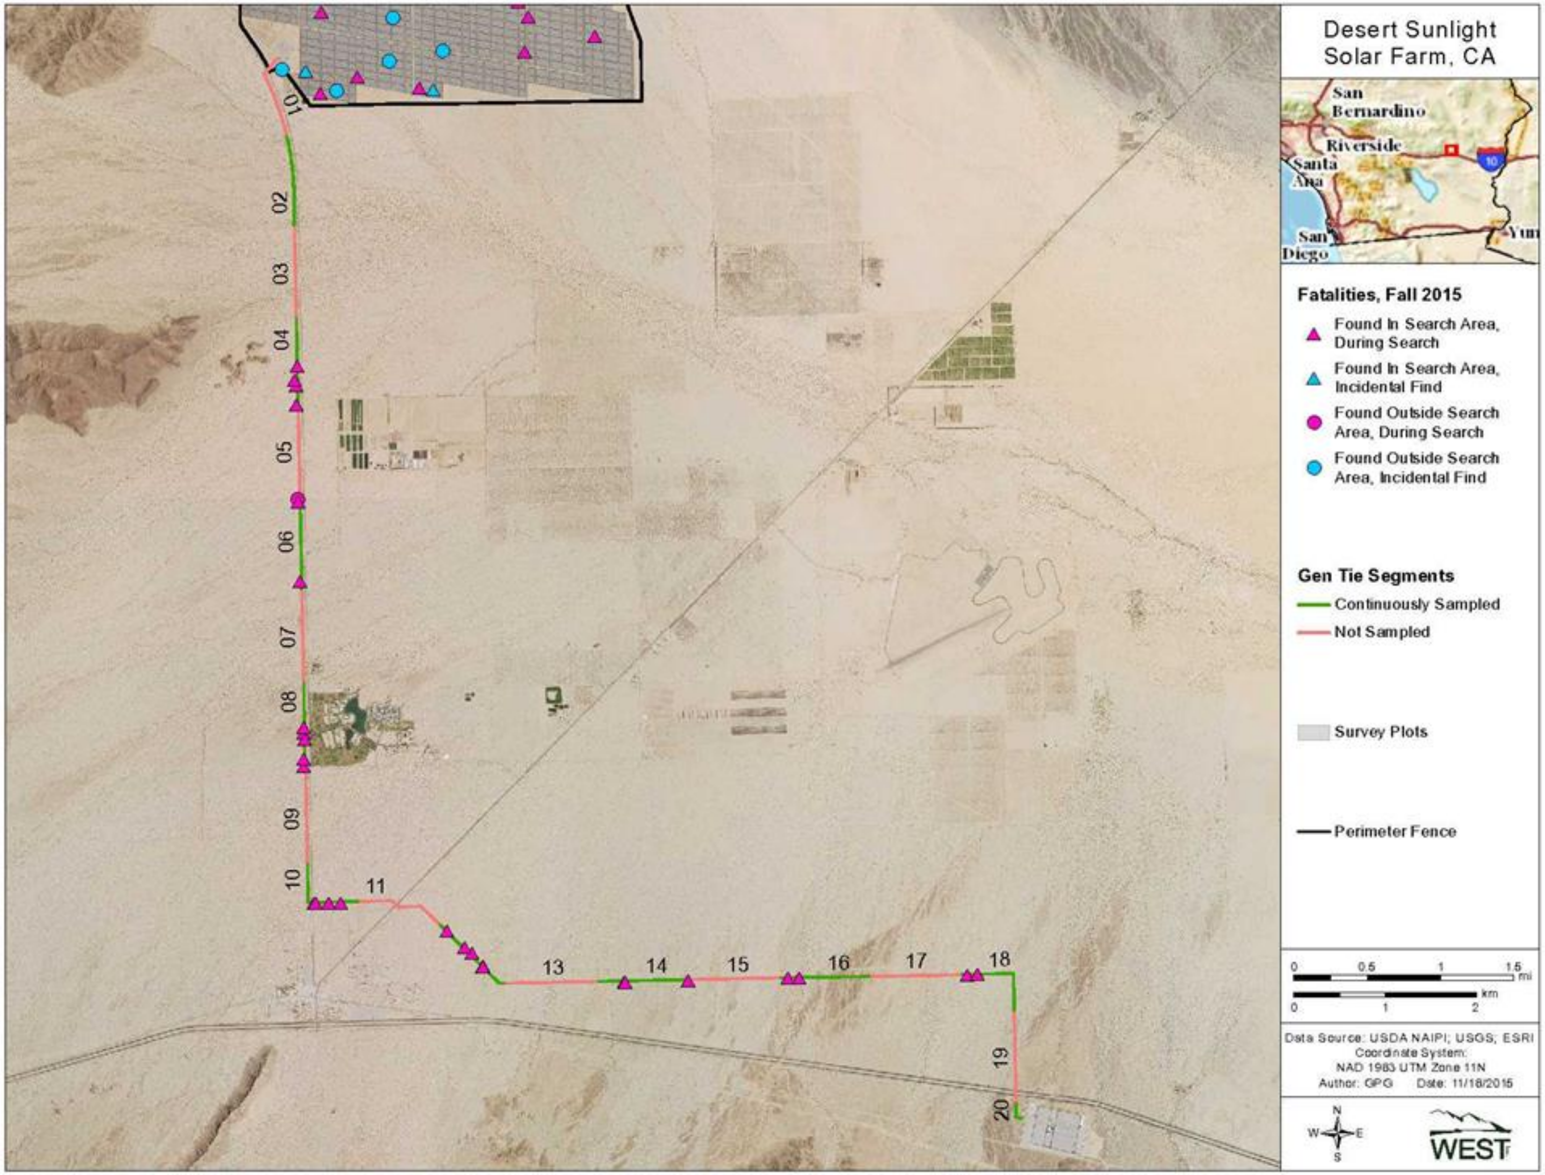
Searched Areas and Locations of Detections Solar Arrays and Fence – Fall 2015



Searched Areas and Locations of Detections Gen-tie Line – Fall 2015



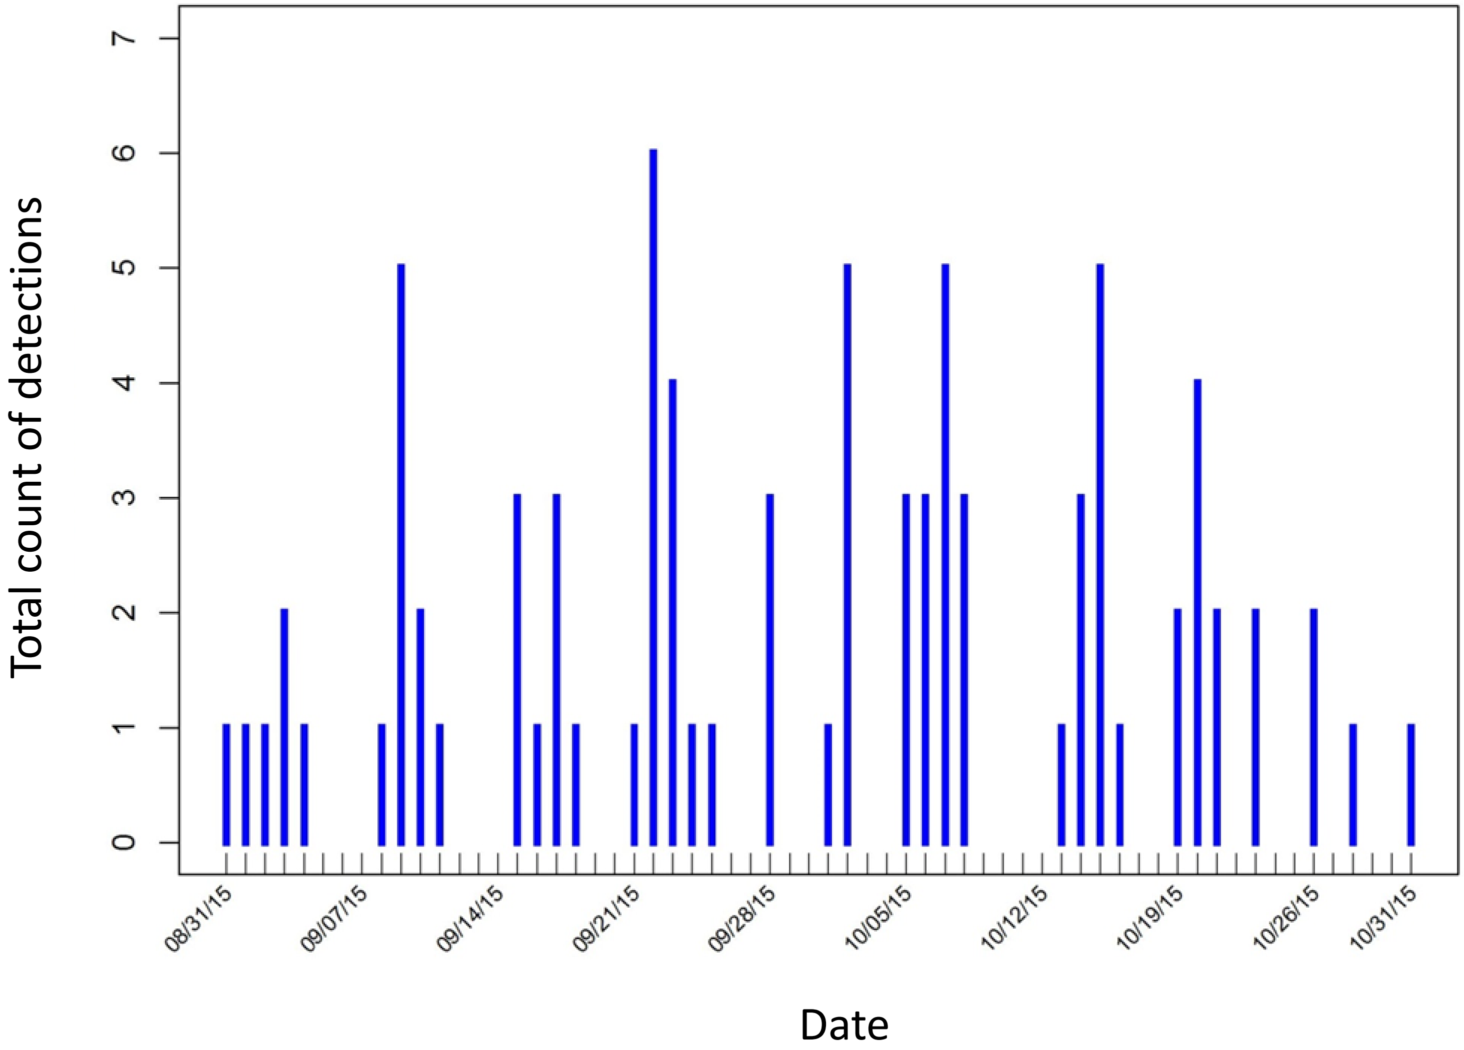
Avian Detections – Fall 2015

- No bats were detected
- Avian
  - 83 total detections (77 carcasses; 6 injured/stranded birds)

Project Component	In search area		Out of search area	
	Carcass search	Incidental	Carcass search	Incidental
Fence	0	0	0	0
Visitor Center	0	0	0	1
Gen-tie line	23	0	5	0
Non-line associated solar arrays	28	5	1	11
Line-associated solar arrays	4	1	1	3
Total	**55**	**6**	**7**	**15**

* 22 detections from this list were excluded from the fatality analysis because they were outside the search area.

Detections by Date – Fall 2015



Detections by Suspected Cause of Death/Injury – Fall 2015

	Suspected Cause *			
Project Component	Collision	Predation	Other/Unknown	% of Total
Fence	0	0	0	**0**
Visitor Center	0	0	1	**1.2**
Gen-tie Line	9	1	18	**33.7**
Solar arrays (line)	2	0	7	**10.8**
Solar arrays (no line)	6	0	39	**54.2**
% of Total	**20.5**	**1.2**	**78.3**	

A suspected cause of death or injury was assigned based on evidence available from the detection, evidence available on Project infrastructure, and proximity of the detection to Project infrastructure. Detections that had evidence of scavenging and lacked evidence on Project infrastructure were assigned as “unknown” because it cannot be determined whether the event was caused by predation or interaction with project infrastructure. Detections that were intact (i.e., no evidence of scavenging) and located in close proximity to Project infrastructure (e.g., found directly beneath overhead lines) had a suspected cause of death attributed to the respective Project component. However, it should be noted that there is substantial uncertainty associated with cause of death assignments because no events were directly observed.

Species Composition – Fall 2015 3+ Detections

- 38 unique species
- American coot most common

Common Name	LA Solar Array	NLA Solar Array	Fence	Gen-tie Line	Visitor Center	Total
American coot	2	7	0	2	0	11
mourning dove	0	2	0	1	1	4
western grebe	0	4	0	0	0	4
ruddy duck	1	2	0	1	0	4
western meadowlark	0	2	0	1	0	3
Eurasian collared-dove	0	0	0	3	0	3
Savannah sparrow	0	1	0	2	0	3
orange-crowned warbler	0	0	0	3	0	3

Feather Spots – Fall 2015

- 14 (17%) of the 83 detections consisted only of feather spots.
  - Gen-tie Line
    - 9 detections (11%)
  - Solar arrays
    - 5 detections (6%)

Fall Reporting Period Summary

- 83 detections
    - 38 species; 13 guilds
    - American coot was most common (11 detections)
        - Most common guilds (no. of detections):
            - Waterbirds/waterfowl (21)
            - Rails/coots (13)
            - Grassland birds/sparrows (12)
            - Warblers (10)
- Detection category
    - 75% were found during scheduled searches
    - 25% were found incidentally

Fence	0	0.00	per km		
Gen-tie*	894 (362 – 2,948)	61.66	per km		
Total	1,190 (636 – 3,265)				

* Very low carcass persistence rates; point estimate and variance estimates are unreliable

Winter Update – Monitoring Effort

- Fourth carcass search occurs this week – two more remains for winter
- First round of carcass persistence trials completed – 2nd ends on Feb. 3
- Searcher efficiency trials completed so far:
  - 34 along gen-tie line
  - 34 in solar arrays
  - 20 along fence
- Continued high removal rates on gen-tie
- Preliminary searcher efficiency similar

Guild Composition – Winter Season – preliminary thru Jan 15

Group	Arrays	Fence	Gen-tie line	Total
Blackbirds/Orioles	0	0	2	2
Grassland/Sparrows	1	0	0	1
Shrikes	2	0	0	2
Unidentified Birds	2	0	0	2
Waterbirds/Waterfowl	9	0	0	9
Woodpeckers	1	0	0	1
Total	15	0	2	17

Species Composition – Winter Season – preliminary through Jan 15

Species	Count
unidentified grebe	6
loggerhead shrike	2
unidentified bird (small)	2
unidentified duck	2
Brewer's blackbird	1
eared grebe	1
northern flicker	1
unidentified sparrow	1
western meadowlark	1

1st Year Effort Summary

- Solar arrays
  - 32 searches X 134 arrays = 4,288 array searches
- Gen-tie line
  - 32 searches X 9, 1-km segments = 288 km of gen-tie searches
- Fence
  - 32 searches X 16.6 km = 534 km of fence searches

Draft Pre-Decisional Document – Privileged and Confidential – Not For Distribution

EXECUTIVE SUMMARY

Avian and bat monitoring surveys were conducted from February 10 to May 31, 2015 (the reporting period) at Desert Sunlight Solar Farm Project (Project) in accordance with the Project's Bird and Bat Conservation Strategy (BBCS). Specifically, standardized carcass searches, searcher efficiency trials, and carcass persistence trials were conducted. This report represents the first seasonal report for the first year of monitoring, and summarizes monitoring methods and results for those surveys based on the procedures and requirements specified in the BBCS.

The spring season at the Project is defined as March 01 to May 31. Included in this report are data from the spring season and data collected from February 10-28. Standardized carcass searches were conducted 1) in the solar field, consisting of a random stratified 29.5% sample of solar photovoltaic (PV) panels, 2) along inner portions of the fenceline, resulting in 74.4% of the length of the perimeter fence, and 3) along 47.9% of the total length of generation-tie (gen-tie) line from the Project fence to the Red Bluff Substation located south of Interstate 10 (I-10). The two searches conducted during February had an interval of approximately 16 days, and searches conducted within the spring season had intervals of approximately seven days.

All bird and bat fatalities and injuries that were discovered by observers, referred to as “detections” in this report, including those found incidentally and during standardized carcass searches, were documented. During the reporting period, 25 avian detections (including 1 injured bird) were made, while there were no detections of bats.

According to specifications of the BBCS, avian detections were categorized by likely diurnal or nocturnal migration behavior, ecological guild (e.g., raptors, songbirds, etc.), facility component, and suspected cause of death. These standardized carcass search results, along with searcher efficiency and carcass persistence rates from bias trials conducted on site, were applied to a fatality estimator model (Huso 2010) to provide a preliminary estimate of the number of fatalities that occurred at the Project during the reporting period adjusted for sources of bias. The estimate is considered preliminary because the annual report may pool information from bias trials and other data across seasons which could affect seasonal estimates.

During the reporting period, carcass persistence was influenced by carcass size and Project component. Small carcasses (0-100 g) in the arrays and along the fence (combined) had a 0.54 probability (90% confidence interval [CI]: 0.47 – 0.61) of persisting through the 7-day search interval, medium carcasses (101 – 999 g) had a 0.82 (90% CI: 0.69 – 0.92) probability, and large carcasses (1000+ g) had a 0.94 (90% CI: 0.88 – 0.98) probability. Mean removal time within the arrays for small, medium, and large carcasses was 5.7, 29.8, and 126.8 days, respectively. Along overhead lines, probability of persistence for small, medium, and large carcasses were 0.29, 0.71, and 0.72, respectively; mean removal time for small, medium, and large carcasses was 2.0, 13.7, and 14.7 days, respectively. Within the solar arrays, searcher efficiency was influenced by carcass size: 60.0% for small birds, 87.2% for medium birds, and

97.3% for large birds. Along the fence, searcher efficiency ranged from 79.3% to 100% depending on carcass size class. Along overhead lines, searcher efficiency ranged from 53.9% to 87.8%.

Using the Huso (2010) fatality estimator model, during the spring period 2015, there were an estimated total 111 fatalities (90% CI: 58 - 193) at the Project. Of these, 49 fatalities (44.1%; 90% CI: 19 – 86) were estimated for the solar arrays, 2 fatalities (1.8%; 90% CI: 2 – 4) were estimated for the fence, and 60 fatalities (54.1%; 90% CI: 16 – 132) were estimated for the overhead lines (gen-tie and medium voltage overhead lines combined). During spring 2015, there were an estimated 0.02 carcasses per acre (49 estimated carcasses/2,585 acres) and an estimated 0.09 carcasses per nameplate MW (49 estimated carcasses/ 550 MW) within the solar field.

1.0 INTRODUCTION

1.1 Project Background

Desert Sunlight 250, LLC and Desert Sunlight 300, LLC (collectively, Desert Sunlight) constructed and operates the Desert Sunlight Solar Farm Project (referred to in this report as "Project"), which consists of two main components: 1) a 550-megawatt (MW) photovoltaic (PV) generating facility; and 2) a 220-kilovolt (kV) generation interconnection (gen-tie) line. The Project comprises approximately 1,700 hectares (ha; 4,200 acres) of land administered by the Bureau of Land Management (BLM) six miles north of Desert Center in Riverside County, California (Figure 1).

1.2 Monitoring Plan Overview and Goals

A Bird and Bat Conservation Strategy (2014; “BBCS”) was prepared by the Project proponent in collaboration with the U.S. Fish and Wildlife Service (USFWS), California Department of Fish and Wildlife (CDFW), (BLM) to guide comprehensive monitoring of impacts to birds and bats associated with operation of the Project. Final agency approval of the BBCS occurred in December 2014.

The BBCS details post-construction monitoring to be conducted and the data analysis and reporting processes that will be implemented by Desert Sunlight in collaboration with the USFWS, CDFW, and BLM. As identified in the BBCS, they are:

1. Estimate overall annual avian fatality rate and species composition associated with the Project infrastructure. This estimate will include mortality associated with solar arrays, overhead lines including the gen-tie line, perimeter fence and other features of the Project that may result in injury and fatality.
2. Determine whether there are spatial and temporal/seasonal patterns of mortality associated with project infrastructure (e.g., different fatality rates near panels on the edge of the arrays vs. the interior area of the arrays).
3. Provide information that will assist the BLM in consultation with the USFWS in understanding which species and potentially which regional populations are at risk.
4. Collect data in such a way that the BLM in consultation with the USFWS may make comparisons with other solar sites.

Figure 1. Desert Sunlight Solar Farm Project vicinity map, Riverside County, California.

1.3 Purpose of This Report

This report represents the first seasonal report for the first year of monitoring summarizing monitoring methods and results for avian and bat fatalities and injuries based on the procedures and requirements specified in the approved BBCS. This report covers the period February 10 to February 28, 2015, as well as the 2015 spring season, which includes the period from March 01 to May 31, 2015. All bird and bat fatalities and injuries that were discovered by observers are referred to as "detections" in this report. As stated in the approved BBCS, this seasonal report includes the observed detections for likely diurnal, and likely nocturnal species, and for ecological guilds of interest (e.g., raptors, water-associated birds, passerines), for each of the facility types and suspected causes of death. Species composition of detections and the results of the bias trials are also reported. This report presents information related to the spatial distribution of detections, but no formal statistical analysis of the spatial distribution of carcasses will be conducted until the end of the monitoring year, given the limited data presently available.

2.0 METHODS

The BBCS describes the methods by which monitoring and certain analyses, including compilation of the overall fatality estimate, will occur. Below is an abridged description (see BBCS for detailed methods).

2.1 Standardized Carcass Searches

This section describes areas surveyed, the timing and frequency of searches, and the methods by which standardized searches were conducted to identify dead/injured birds and bats at the Project. Dead or injured birds and bats are called detections in this report to provide consistency in naming. This section also describes the methods for conducting carcass removal and searcher efficiency trials; how data were reported and analyzed; and the methods for producing fatality estimates for the Project.

2.1.1 *Areas Surveyed*

Standardized carcass searches were conducted at sampling units, which include the solar arrays; the "fenceline" defined as the perimeter fence for the Project (Table 1, Figure 2); and the gen-tie line (from the Project fence to the Red Bluff Substation on the south side of I-10; Table 1, Figure 3). Some overhead lines co-occur with solar arrays (medium voltage overhead lines [MVOH]). The MVOH were part of standardized carcass searches to the extent that they co-occured with solar arrays included in the sample. Table 1 provides the total area of each component as well as the percent of each component that was searched.

Table 1. Areas included in standardized carcass searches at the Desert Sunlight Solar Farm Project during spring 2015 (including February).

Project Component	Total Size	Units	% of Component Searched
Solar arrays	1045.9	Hectares	28.2[1]
Solar arrays	1045.9	Hectares	1.3[2]
Solar arrays	1045.9	Hectares	1.3[3]
Fence	16.7	Kilometers	99%[4]
Gen-tie line	19.2	Kilometers	47.9[5]

[1] Percent area that was searched continuously since monitoring commenced in February 2015. Slightly less than 30% total (including areas affected by the tornado) because of unequal size arrays.

[2] Percent that was searched before the April 21, 2015 tornado but not after.

[3] Percent that was searched after the tornado but not before.

[4] 74.4% of the fence is fully accessible and surveyed following the standard protocol, while approximately 25% of the fence is surveyed from a distance. A very short segment near the gate is not sampled due to restoration activities

[5] 52.1% of gen-tie will be sampled in 2016.

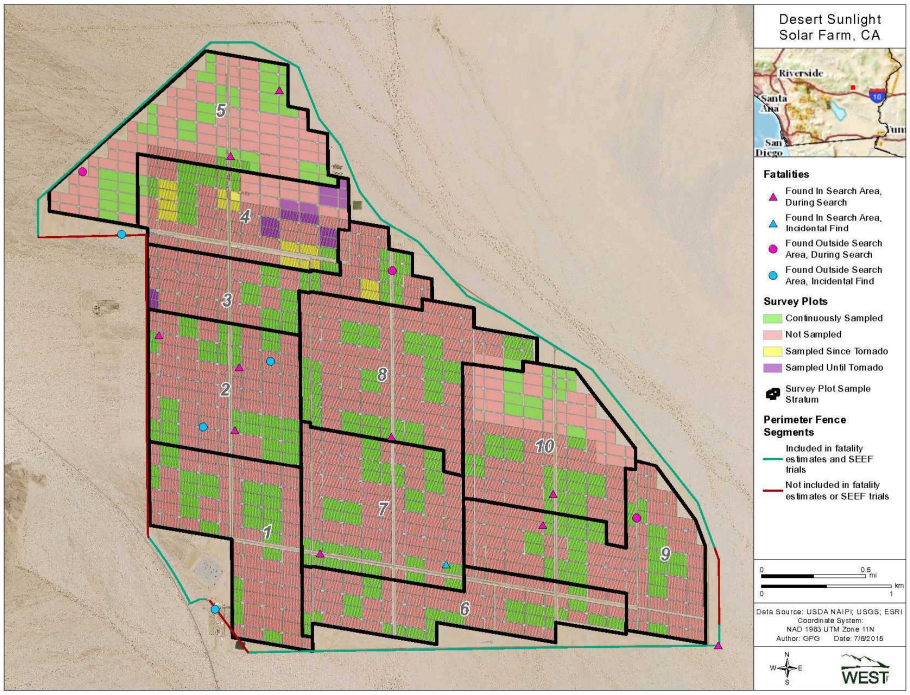

Figure 2. **Areas of standardized searches and detections (those made during searches and those made incidental to operations and maintenance) at the solar field, fence, and overhead lines within the fence at Desert Sunlight Solar Farm Project during spring 2015 (including February). Because of the presence of medium voltage overhead lines within the solar arrays, some detections within the arrays were assigned to overhead lines.**

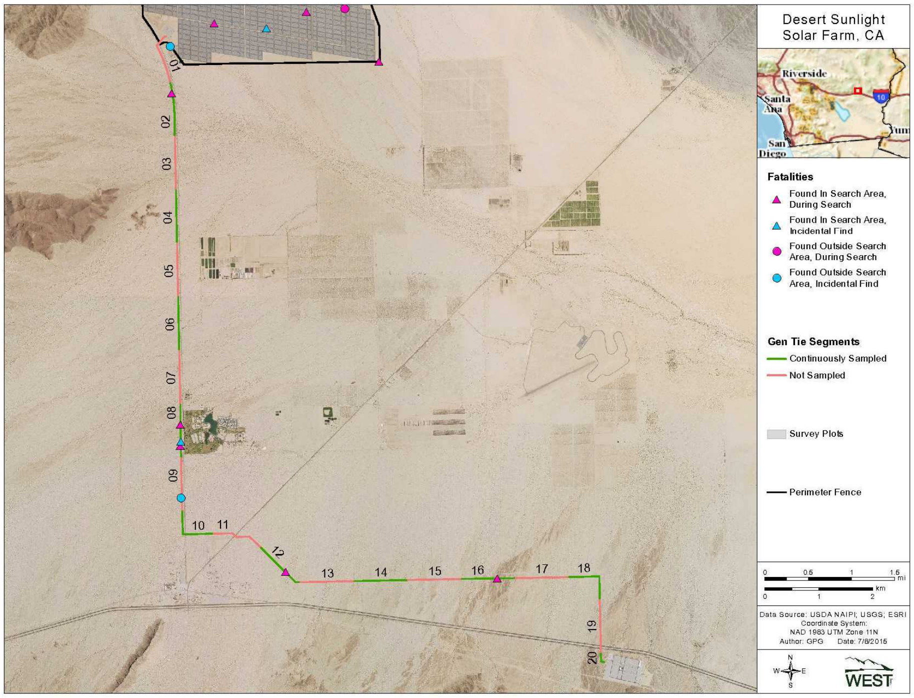

Figure 3. Areas of standardized searches and detections (those made during searches and those made incidental to operations and maintenance activities) along the generation tie line at the Desert Sunlight Solar Farm Project during spring 2015 (including February). Detailed maps of detections along the line are presented in Appendix A.

To ensure a balanced distribution of sample units in the solar field (defined as the collection of all photovoltaic [PV] solar panels), the entire field was divided into ten strata, and individual sampling units were randomly selected within each stratum to compose an approximately 30% sample. The solar field consists of arrays of solar panels (referred to as a solar array). This sampling design ensures that units included in the sample were not spatially clumped within the solar field.

2.1.1 *Search Frequency and Timing*

Standardized searches began February 10, 2015 (during the winter season outlined in the BBCS). The spring survey season includes the period from March 01 through May 31, 2015. All project components included in standardized searches were surveyed 14 times from February 10 to May 31, 2015 (twice in February and 12 times during spring).

The average search interval for all Project components included in standardized carcass searches during February was 16.1 days (median 15 days), and during spring was 7.1 days (median 7 days). Slight variation in search interval was anticipated due to weather and logistical delays. On April 21, 2015, the Project was struck by a tornado. The tornado damaged some of the sampling units, and resulted in limited access that ultimately lasted longer than initially expected. Thus, 142 sample units (128 arrays, fence, and gen-tie combined) were visited 14 times continuously and without interruption during the reporting period (two times in February and 12 times in spring). Six arrays were visited seven times before the tornado occurred; 3 weeks elapsed before the six damaged arrays were replaced with undamaged arrays. Five of the replacement arrays were visited twice and one was visited once.

2.1.2 *Search Methods*

Standardized carcass searches were performed by BLM-approved biologists, in accordance with methods outlined in the BBCS.

Within the solar field, arrays of solar panels were surveyed by observers traveling on foot. A distance sampling approach was used, whereby biologists slowly walked a transect line along the ends of rows of solar panels in a direction perpendicular to the rows, searching ahead and to the side within the array for bird and bat detections. Biologists scanned out to a maximum perpendicular distance of approximately 70 m from the transect. Biologists carried binoculars to allow them to verify the presence of a detection versus rocks or vegetation. Once a detection was confirmed, the distance of the detection to the transect line was estimated using laser range finders. Each array included in the sample was searched by observers walking two transects – one on the west side and one on the east side of the array.

Comentado [MR1]: 229 ft

Most (74.4%) of the length of fenceline (approximately 10 miles) was searched from a vehicle using the standard protocol (Figure 2). Biologists searched a 6-m wide strip transect centered on the fence from the inner perimeter. Travel speed was below five miles per hour (mph) while searching. Some sections along the fence cannot be driven close to the fence line. The fence line along the western edge of the Project is drivable but the road is approximately 15 m away from the fence and the road and fence are separated by a drainage ditch. The fence along this section is covered with a tan tarp to block and trees and shrubs have been planted to reduce visibility of the project from the west. Additions of vegetation and the tarp likely reduce potential for bird collision with the fence. This section of the fence was driven to document carcasses, but detections along this portion of the fence are not included in adjusted fatality estimates because detection rates are likely very low. A separate section of the fence in the southeastern corner of the Project cannot be driven because the eastern edge of the berm that bounded construction ponds is too narrow for a vehicle. Along this portion of the fence, the observer stopped at both north and south ends of the berm and used binoculars to search for carcasses. Finally, the road along a portion of the southwest fence line near the entrance gate is approximately 30 to 50 m from the road and is separated from the fence by an area that has recently undergone vegetation restoration. This area was eliminated from sampling. Fatality rates estimated for sections of the fence that were sampled were extrapolated to sections of the fence where the standard monitoring protocol was not used.

The gen-tie line was searched using a 30-m wide strip transect (i.e., 15 m of ground on either side of the overhead line). Sample units along the gen-tie line were chosen by dividing the total length of line from the Project fence south to the Red Bluff Substation just south of I-10 into 1-km segments. Thus, a 47.9% sample of the total length of the line was searched (Figure 3). Biologists slowly walked every other 1-km segment of the line, meandering the width of the strip transect, scanning for dead or injured birds or bats within 15 m (49.2 ft) of the overhead line.

For each detection, a suspected cause of death or injury was assigned based on available evidence and proximity of a detection to Project infrastructure. Detections that had evidence of scavenging were assigned as “unknown” because it cannot be determined whether the event was caused by predation or interaction with project infrastructure. Detections that were intact (i.e., no evidence of scavenging) and located in close proximity to Project infrastructure (e.g., found directly beneath overhead lines) had a suspected cause of death attributed to the respective Project component. However, it should be noted that there is substantial uncertainty associated with cause of death assignments because no events were directly observed.

2.2 Carcass Persistence Trials

Carcass persistence trials were conducted throughout the spring period. Carcasses from three size classes (small [0-100 g], medium [101-999], and large [1000+ g]) were used for trials. The small size class comprised house sparrows (*Passer domesticus*) and 2-3 week old coturnix quail (*Coturnix coturnix*), the medium size class comprised rock pigeons (*Columba livia*), and the large size class comprised hen mallard (*Anas platyrhynchos*) and hen ring-necked pheasant (*Phasianus colchicus*).

2.2.1 *Carcass Persistence Data Collection*

To quantify carcass persistence rates, 15 small, 10 medium, and 5 large carcasses were randomly placed and monitored along the gen-tie line during spring 2015. Within the solar arrays and along the perimeter fence, the same numbers of small and medium carcasses were placed, along with 10 large carcasses, for a total of 65 carcass persistence trials at Desert Sunlight during the spring season. Thirty-five carcasses within the Project fence (within solar arrays and along the fence) were monitored using motion-triggered digital trail cameras, while the remaining carcasses were visited on foot, for 30 days or until the carcass had deteriorated to a condition at which it would no longer qualify as a documentable fatality. No carcasses along the gen-tie line were monitored with cameras because of theft and vandalism concerns. Carcasses without trail cameras were visited and photographed once per day for the first four days, and then every three to five days until the end of the monitoring period. To avoid training scavengers to recognize cameras as “feeding stations”, trail cameras were installed five days before specimens were placed, and two fake cameras without bias trial carcasses were also placed within the Project fence and periodically moved to new locations within the fence. Periodic ground-based checking of carcasses with trail cameras also occured to guard against misleading indicators of carcass removal, such as wind blowing the carcass out of the camera’s field of view. To minimize potential bias caused by scavenger swamping (Smallwood 2007, Smallwood et al. 2010), carcass-persistence specimens were distributed across the entire

Project, not just in areas subject to standard searches, and trials were initiated in small numbers on six different dates throughout the spring season.

In February, 15 (n = 7 small, 5 medium, and 3 large) carcass persistence trials were placed in the solar arrays and along the Project fence, and 15 trials (n = 8 small, 5 medium, and 2 large) were placed along the gen-tie line. Eight carcasses within the arrays and fence were monitored with trial cameras, and four fake cameras were placed within the arrays and along the fence. Carcass persistence trials were initiated on two different dates in February.

2.2.2 *Estimating Carcass Persistence Times*

Measurements of carcass persistence rates were subject to censoring. In this context, censoring refers to the instance when a value (e.g. days a carcass is present before being removed) may not be known exactly, but is known to be within a finite range. For example, suppose a carcass was checked on day 7 and was present, and was checked again on day 10, but was found to be missing. The exact time until removal is unknown; however, it is known that the carcass was available to be found for between 7 and 10 days. This carcass would be considered “interval censored”. Similarly, if a carcass lasts the entire 30-day trial period, that carcass is “right censored”— it is known that the carcass lasted at least 30 days, but it may have persisted longer.

There were four distributions implemented in survival models used to estimate the probability a carcass is unscavenged and available to be found at the end of the search interval (r): exponential, Weibull, loglogistic, and lognormal. These four distributions exhibit varying degrees of flexibility in order to model a wide variety of distributions of persistence time. Akaike’s Information Criterion adjusted for sample size (AICc; Akaike 1973) was used to rank the fit of each survival model with combinations of the covariates carcass size, location, and visibility, to observed carcass persistence data.

2.3 Searcher Efficiency Trials

Searcher efficiency trials were conducted throughout the spring period (including February). Carcasses from three size classes (small, medium, and large) were used for trials. The small size class comprised house sparrows and 2-3 week old coturnix quail (*Coturnix coturnix*), the medium size class comprised rock pigeons, and the large size class comprised hen mallards and hen ring-necked pheasants.

2.3.1 *Searcher Efficiency Data Collection*

Training of biologists on the Project-specific protocol and early assessments of habitat conditions at the Project site suggested that the amount of cobble present in the soil may be an important factor influencing searcher efficiency. To satisfy requirements regarding consideration of visibility class per the BBCS and address the influence of cobble cover on searcher efficiency, sample units in the solar arrays and along the gen-tie were stratified by cobble cover and assigned to one of two classes (<15% and >15% cobble cover). Classes were determined by making ocular estimates of cobble cover at each sample unit and then evaluating the frequency histogram of sample units across the range of estimated cobble cover (Figure 4). A natural break point was identified at 15% cobble cover, so the same value was chosen as the break point that defined the two strata. In the solar arrays, one set of searcher efficiency trials (*n* = 15 small birds, 10 medium birds, and 5 large birds) was conducted in each strata. Similarly, searcher efficiency trials along the gen-tie occurred in two visibility strata (easy: ≥90% bare ground, vegetation <6" tall; and more difficult: <90% bare ground, vegetation ≥6" tall). Thirty searcher efficiency trials (*n* = 15 small birds, 10 medium birds, and 5 large birds) occurred along the fence in the only stratum present on the fence (easy visibility). Thus, in February, a total of 150 searcher efficiency trials occurred at the Project, and the same methods and number occurred during the spring season. Locations for trials were chosen by taking a randomized sample of all locations included in standardized carcass searches.

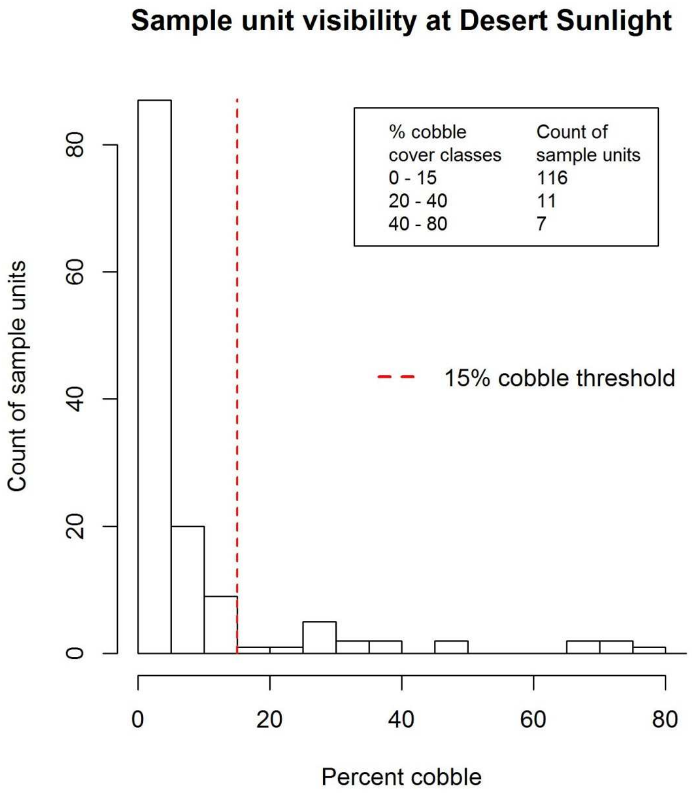

Figure 4. Frequency histogram of sample units (in the arrays only) at Desert Sunlight Solar Farm Project by estimates of cobble cover. Based on this distribution, each sample unit was assigned to one of two classes of cobble cover (<15%; >15%).

2.3.2 *Estimating Searcher Efficiency*

Searcher efficiency at Desert Sunlight was estimated separately for linear features (the project fence and the generation tie line), and the solar arrays, reflecting the different search methods used on arrays and linear features. For linear features, logistic regression models were fit to searcher efficiency data and AICc was used to compare models. Models including effects of carcass size (three classes) and visibility (two classes; gen-tie only), were compared to each other and the null model. Model selection indicated that best models accounted for component, carcass size, and on the gen-tie line, visibility. Once the best model was chosen and appropriate classes identified, searcher efficiency, or the proportion of carcasses detected, *p*, was calculated for each class using the following equation:

$$p = \frac{Number\ of\ Carcasses\ Observed}{Number\ of\ Carcasses\ Available}$$

The data for this analysis included all searcher efficiency trial carcasses from February and the spring 2015 season.

For the solar arrays, searcher efficiency was evaluated using a distance sampling approach (Buckland et al. 1993). Distance sampling assumes perfect detection on the transect line (at distance = 0), an assumption that is likely valid in the solar arrays given the relatively flat & vegetation-free nature of the soil surface. A curve is fitted to the observed carcass data that predicts probability of detection as a function of distance from the transect line. The mean value of this function over a specified distance, *w,* is equal to the average searcher efficiency for a transect of width *w*. One departure in the methods used here, relative to the methods presented in Buckland et al. (1993), was that for this study the detection function was estimated using trial carcasses, which meant that there were both presence (detected) and absence (not detected) data available to fit the detection function (Figure 5). The availability of both presence and absence data means that the detection function can be estimated using only trial carcasses whose distribution is known. Therefore the detection function, the average searcher efficiency among the arrays and the final fatality estimate within the arrays are all insensitive to the spatial distribution of carcasses within individual arrays, and the overall searcher efficiency estimate is valid even if the distribution of carcasses among the arrays is not uniform.

Distances of trial carcasses (trials both found and missed) from the transect line were used to fit a half-normal detection function for searches among the arrays (Figure 5). The half-normal detection function is a commonly used function for distance sampling surveys (Buckland et al. 1993). The detection function was fit with and without covariates (carcass size, visibility index, or no covariates) and AICc indicated that the best among these models included only carcass size as a covariate.

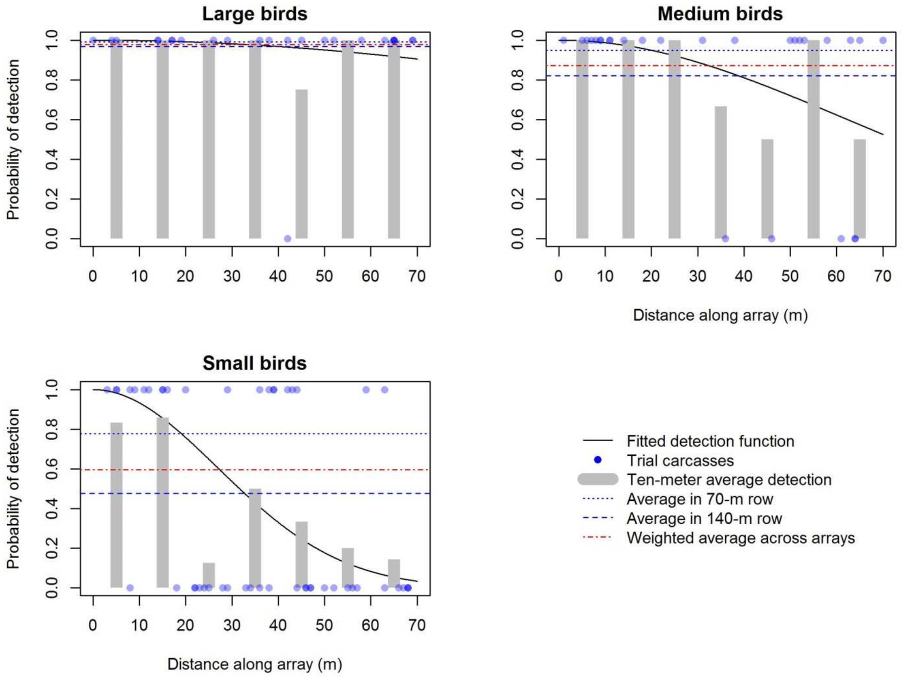

Figure 5. Estimated detection probabilities for bird carcasses by size class during spring 2015 (including February) at the Desert Sunlight Solar Farm Project, Riverside County, California. Distance sampling was used when searching solar arrays only. Average probability of detection over 70-m and 140-m panel rows in solar arrays are presented.

Because the solar arrays were surveyed by searchers who walked down both sides of the rows of panels, the width of the search transect was specified as half the width of the rows of panels. For larger birds, there is almost certainly a non-zero detection probability beyond this distance but the bias that occurs by ignoring this non-zero detection probability is conservative (i.e. the searcher efficiency is underestimated). Some solar arrays have row widths of 70 m (search transect width of 35 m) and some have row widths of 140 m (search transect width of 70 m). Searcher efficiency was higher for the arrays with a width of 70 m, and overall searcher efficiency was estimated as a weighted average based on the proportions of 70-m arrays and 140-m arrays in the sample units.

2.4 Fatality Estimator

Fatality rate estimation is a complex task due to several variables inherent to every fatality monitoring study. Carcasses may persist for variable amounts of time due to local scavenger activity or environmental conditions leading to carcass degradation over time. Carcasses and feather spots are also detected with varying levels of success based on carcass characteristics and ground cover (e.g., vegetated areas underneath the gen-tie line versus cleared areas beneath solar panels). For these reasons, it is generally inappropriate to draw conclusions based on the raw number of fatalities alone. The desire to estimate fatalities given these variables has driven the development of several statistical methods for estimating fatalities (e.g., Smallwood 2007, Huso 2010, Korner-Nievergelt 2011). All of these fatality estimation methods share a similar underlying model. Generally, the fatality estimation for a given site may be written as:

$$F=C/rp,$$

where F is the total number of fatalities, C is the number fatalities detected and included in fatality estimation, r is the probability a carcass is unscavenged and available to be found at the end of the search interval, and p is the probability of detecting a carcass (Huso 2010).

All fatality estimates were calculated using the Huso estimator, as well as 90% confidence using bootstrapping (Manly 1997). Bootstrapping is a computer simulation technique that is useful for calculating point estimates, variances, and confidence intervals for complicated test statistics. A total of 1,000 bootstrap replicates were used. The lower 5th and upper 95th percentiles of the 1,000 bootstrap estimates provide estimates of the lower limit and upper limit of an approximate 90% confidence interval on all estimates.

2.5 Incidental Reporting

Some detections were outside standardized search areas, or were within search areas but not observed during standardized searches. Such detections were found by WEST avian biologists and operational personnel and were considered “incidental” detections. When found by operational personnel, these detections were reported to WEST avian biologists for documentation. Data on incidental detections are reported here, as well as in the Desert Sunlight SPUT Avian Injury and Mortality Report Forms February – May 2015. All detections made in search areas were included in fatality estimates, regardless of whether they were detected incidentally or during searches.

3.0 MONITORING RESULTS

3.1 Summary of Avian Detections

During spring 2015 (including February), a total of 25 avian detections (including one injured bird and incidentals) of 13 identified species were recorded (Table 2). The most numerous detection of an identified species was common loon (*Gavia immer*), but with only four detections. Most detections (n = 12, or 48.0% of total detections) occurred in the solar arrays (Figures 2 and 3; Tables 2, 3, and 4). Eighteen (72%) detections were made during standardized carcass searches and seven (28.0%) were documented as incidentals. For fresh carcasses, body weights and weather conditions the preceding nights are described in Appendix B.

Table 2. Number of individual bird detections, by species, during spring 2015 (including February) at the Desert Sunlight Solar Farm Project, Riverside County, California. Overhead lines include the gen-tie line and medium voltage overhead lines that co-occur with the solar arrays.

Common Name	Scientific Name	Migration Behavior*	Guild	Count	Project Component
common loon	*Gavia immer*	diurnal	waterbirds/waterfowl	4	solar arrays

Table 2. Number of individual bird detections, by species, during spring 2015 (including February) at the Desert Sunlight Solar Farm Project, Riverside County, California. Overhead lines include the gen-tie line and medium voltage overhead lines that co-occur with the solar arrays.

Common Name	Scientific Name	Migration Behavior*	Guild	Count	Project Component
white-winged dove	*Zenaida asiatica*	variable	doves/pigeons	1	fence
				2	overhead lines
Wilson's warbler	*Cardellina pusilla*	nocturnal	warblers	1	overhead lines
Total				**25**	

* See literature cited for migration behavior references; information for most species was taken from the respective species accounts found in Birds of North America (BNA) Online (http://bna.birds.cornell.edu/bna/); where information on migration behavior was lacking in BNA accounts, Newton (2008) or Murray (2004) were used.

Table 3. Total avian detections by Project component and detection category during spring 2015 (including February) at the Desert Sunlight Solar Farm Project, Riverside County, California. Overhead lines includes the gen-tie and medium voltage overhead lines that co-occur with the solar arrays. Only carcasses found within search areas were included in fatality estimates.

	Inside carcass search area		Outside carcass search area	
Project Component	**Carcass search**	**Incidental**	**Carcass search**	**Incidental**
Fence	1	0	0	1
O&M Building	0	0	0	1
Overhead lines	7	1	0	1
Solar arrays	6	1	3	2

Table 4. Total avian detections (including incidentals) by Project component and suspected cause of death during spring 2015 (including February) at the Desert Sunlight Solar Farm Project, Riverside County, California. Overhead lines includes the gen-tie and medium voltage overhead lines that co-occur with the solar arrays.

	Suspected Cause of Death*				
Project Component	**Collision**	**Predation**	**Other**	**Unknown**	**Percent of Total**
Fence	1	0	0	1	8.0
O&M building	0	0	1	0	4.0
Overhead lines	7	1	1	1	40.0
Solar arrays	1	0	4	7	48.0
Percent of Total	**36.0**	**4.0**	**24.0**	**36.0**	**100.0**

* Suspected cause of death was assigned based on available evidence and proximity of detection to Project infrastructure. Detections that had evidence of scavenging were assigned as "unknown" because it can't be determined whether the event was caused by predation or interaction with project infrastructure. Detections that were intact (i.e., no evidence of scavenging) and located in close proximity to Project infrastructure (e.g., found directly beneath overhead lines) had a suspected cause of death attributed to the respective Project component. However, it should be noted that there is substantial uncertainty associated with cause of death assignments because no events were directly observed.

3.2 Temporal Patterns of Avian Detections

The number of detections recorded daily during the reporting period ranged from zero to two (Figure 6). The period from March 30 to May 27 was characterized by slightly higher numbers of detections with more days with two detections than the previous period. The number of detections per day represents those discovered during standardized carcass searches and incidentally.

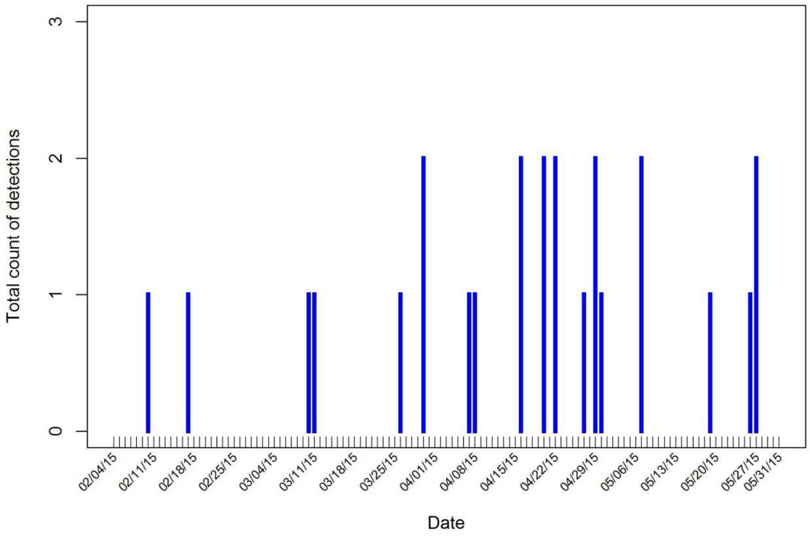

Figure 6. Total number of detections by date during spring 2015 (including February) at the Desert Sunlight Solar Farm Project, Riverside County, California.

3.3 Spatial Distribution of Avian Detections

3.3.1 *Detections by Project Component*

During the reporting period, detections were documented from the solar arrays, perimeter fence, gen-tie line, MVOH lines within the solar field, and the O&M building (Tables 2, 3, and 4). Of the 12 detections within the solar arrays, most (7, or 58.3%) were assigned to the "unknown" category for suspected cause of death.

3.3.2 *Feather Spot Detections*

Eight (32.0%) of the 25 detections consisted only of feather spots. Along the fence, one detection (4.0%) was a feather spot. Three detections (12.0%) along the overhead lines were feather spots. Four detections (16.0%) in the solar arrays were feather spots.

3.4 Detections of Injured Birds

One bird was located during the reporting period that was injured. A mourning dove (*Zenaida macroura*) was discovered on April 22 along the northern section of the perimeter fence. The bird had an obvious injury to its breast. Because the bird was found the day after the tornado struck the Project, the injury may have been a result of the storm. The bird was taken to Coachella Valley Wild Bird Center and left with Linda York for rehabilitation. Numerous attempts to determine the final outcome for the dove were unsuccessful. The single injured bird detection was included in the fatality estimates.

3.5 Summary of Bat Detections

No bats were located during the spring 2015 season (including February).

3.6 Carcass Persistence Trials

Based on carcass persistence data from the spring 2015 season, 20 survival models were compared for relative quality using the corrected AICc score, as suggested in Huso (2010). The AICc score provides a relative measure of model fit and parsimony among a selection of candidate models. Carcass size is a potentially important variable, as larger carcasses tend to persist longer and may be more likely to leave feather spots which persist for long durations, whereas smaller carcasses may be more likely to be completely removed.

The model with lowest AICc score is typically chosen as the “best” model relative to other models tested; however, any model within two AICc points of the best model is considered competitive with the best model (Burnham and Anderson 2004). The top model had a ∆AICc value of 2.84 and included carcass size (small, medium or large), and location (solar arrays/fence or generation-tie line) with a Weibull-distributed removal time. Estimates of carcass removal time and persistence probabilities are provided in Table 5.

Table 5. Mean carcass removal time and probability of a carcass persisting through the 7-day search interval during the reporting period at the Desert Sunlight Solar Farm Project, Riverside County, California.

Carcass size	Project component	Mean removal time (days)	Probability of persistence
Small	Arrays/fence	5.7	0.54
Small	Overhead lines	2.0	0.29
Medium	Arrays/fence	29.8	0.82
Medium	Overhead lines	13.7	0.71
Large	Arrays/fence	126.8	0.94
Large	Overhead lines	14.6	0.72

Comentado [MR2]: How do you get 126 days?

3.7 Searcher Efficiency Trials

During the reporting period, a total of 300 searcher efficiency trials were placed at the Project. Most trials were available to be found, but some disappeared before or during the trial. Overall, 120 trials were placed in the solar arrays and 102 were available to be found; 60 trials were placed along the perimeter fence (inner perimeter only) and 59 were available to be found; and 120 trials were placed along the gen-tie line and 105 were available to be found.

In the solar arrays, the model that included an effect of carcass size was chosen as the best model to estimate searcher efficiency. Within the solar arrays, searcher efficiency was influenced by carcass size: 60.0% for small birds, 87.2% for medium birds, and 97.3% for large birds. Along the fence, searcher efficiency ranged from 79.3% to 100% depending on carcass size class. Along overhead lines, searcher efficiency ranged from 53.9% to 87.8%. Detailed estimates of searcher efficiency estimates specific to each component and carcass size are reported in Appendix C.

3.8 Fatality Estimates

Fatality estimates were calculated separately for each component (solar arrays, fence, and overhead lines). Ultimately, nine detections were excluded from the fatality analysis: five were found outside standardized search areas; one was estimated to be older than the 7-day search interval (Huso 2010); and three were both outside standard search areas and estimated to be older than the 7-day search interval.

During spring 2015, there were an estimated total 111 fatalities (90% CI: 58 - 193) at the Project. Of these, 49 fatalities (44.1%; 90% CI: 19 – 86) were estimated for the solar arrays, 2 fatalities (1.8%; 90% CI: 2 – 4) were estimated for the fence, and 60 fatalities (54.1%; 90% CI: 16 – 132) were estimated for the overhead lines (gen-tie and medium voltage overhead lines combined). There were an estimated 0.02 fatalities per acre (within the solar field only) and an estimated 0.20 fatalities per nameplate MW at the Project. A complete list of estimates for each Project component and carcass size class with confidence intervals is presented in Appendix C.

4.0 DISCUSSION

The 2015 spring season represented the first full season of standardized monitoring at Desert Sunlight per the BBCS. Searcher efficiency trials and carcass removal trials were conducted concurrently at the solar arrays, fencelines, and along the gen-tie line. Data from these trials were used to produce fatality estimates adjusted for searcher efficiency and carcass persistence bias. Although these estimates were produced from a statistically robust sample, only limited inference may be drawn from a single season of data. These results should be considered preliminary because estimating carcass persistence, searcher efficiency, and adjusted numbers of fatalities within each season represents information based on a limited sample size. As more data are collected throughout the monitoring year (and additional quality assurance/quality control measures occur, for example characterizing feather spots to species or size class), data from all seasons may be pooled. At that time, data will be tested for seasonal differences retrospectively, but because seasonal estimates will be produced from the much larger annual data set, they may differ from what is reported here because they are based on a larger, more informative sample.

4.1 Carcass Persistence and Searcher Efficiency Trials

The degree to which carcasses persist on the landscape depends on a variety of factors reflecting seasonal and inter-annual variation in habitat, climate, and the scavenger community. The composition and activity patterns of the scavenger community often vary seasonally as birds migrate, new juvenile birds and mammals join the local population, and mammalian scavengers variably hibernate or estivate. The scavenger community may also vary substantially from year to year because of variation in annual reproduction and survival related to changes in landscape condition. Climatic conditions that vary seasonally and annually also may contribute to variation in carcass decay and removal rates due to variation in temperatures, solar insolation, wind patterns, and the frequency of flooding events. Thus, rates of carcass persistence reported here should be interpreted cautiously as they may change over the coming months.

Searcher efficiency was influenced by Project component, carcass size, and visibility class (along the gen-tie only). In the solar arrays, searcher efficiency was high (> 0.5) for all carcass size classes and this is likely influenced by the limited vegetation cover beneath solar panels. Beneath the gen-tie line vegetation cover is higher in some portions of the strip transects, and results reported here support the hypothesis that visibility class is a factor in searcher efficiency along the lines.

For the current analysis, searcher efficiency in the solar arrays was assumed to be best predicted by a half-normal distribution. For future analyses, AICc will be used to compare and choose the best among multiple detection functions.

Searcher efficiency trials for this Project will be repeated seasonally. The desert landscape in which this Project is located generally changes little with the seasons, save for brief periods following winter and spring rains when floods may occur and blooming plants may flourish. A recent meta-analysis involving data from more than 70 wind-energy projects suggested that including habitat visibility class as a predictive variable generally eliminated any otherwise apparent seasonal effects on searcher efficiency (Smallwood 2013). Further, the possibility exists that searcher efficiency varies seasonally in some cover types but not others. Data from searcher efficiency trials conducted over the coming seasons will therefore continue to be tested for effects of habitat visibility class rather than effects of season.

4.2 Distribution of Fatalities and Fatality Estimates

The number of detections was more or less evenly distributed across the spring season, and there were no clear associations between number of detections and date. Given the small number of detections overall, it is premature to draw any conclusions about the spatial distribution of carcasses.

Detections attributed to an unknown cause accounted for 36.0% of all detections during the reporting period, and the distribution of the unknown cause detections varied by project component with 48.0% occurring in association with the solar arrays. Of the 12 detections made in the solar arrays, 16.0% were feather spots. Determining a cause of mortality from a feather spot is challenging because there is rarely visible evidence available on which to determine a cause of death. Thus, feather spots with an unknown cause of mortality could be encountered anywhere birds occur, and an unknown cause of a sizeable proportion of the carcasses is not unique to the Project. Further, the relatively large proportion of feather spots (32%) among the detections for the Project as a whole may inflate the fatality estimate when unknown cause detections are included based on the potential for multiple feather spots resulting from one fatality, feather spots resulting from predation not associated with the facility, or other causes.

Draft Pre-Decisional Document - Privileged and Confidential - Not For Distribution

EXECUTIVE SUMMARY

Avian and bat monitoring surveys were conducted from February 10 to May 31, 2015 (the reporting period) at Desert Sunlight Solar Farm Project (Project) in accordance with the Project's Bird and Bat Conservation Strategy (BBCS). Specifically, standardized carcass searches, searcher efficiency trials, and carcass persistence trials were conducted. This report represents the first seasonal report for the first year of monitoring, and summarizes monitoring methods and results for those surveys based on the procedures and requirements specified in the BBCS.

Included in this report are data from standardized carcass searches conducted during the spring season at the Project, defined as March 01 to May 31, 2015. . Standardized carcass searches were conducted 1) in the solar field, consisting of a random stratified 29.5% sample of solar photovoltaic (PV) panels, 2) along inner portions of the fenceline, resulting in 74.4% of the length of the perimeter fence, and 3) along 47.9% of the total length of generation-tie (gen-tie) line from the Project fence to the Red Bluff Substation located south of Interstate 10 (I-10). Searches conducted within the spring season had intervals of approximately seven days, and all searches were conducted during daylight hours.

All bird and bat fatalities and injuries that were discovered by observers, referred to as "detections" in this report, including those found incidentally and during standardized carcass searches, were documented. During the reporting period, 23 avian detections (including 1 injured bird) were made, and there were no detections of bats.

According to specifications of the BBCS, avian detections were categorized by likely diurnal or nocturnal migration behavior, ecological guild (e.g., raptors, songbirds, etc.), facility component, and suspected cause of death. These standardized carcass search results, along with searcher efficiency and carcass persistence rates from bias trials conducted on site, were applied to a fatality estimator model (Huso 2010) to provide a preliminary estimate of the number of fatalities that occurred at the Project during the reporting period adjusted for sources of bias. The estimate is considered preliminary because the annual report may pool information from bias trials and other data across seasons which could affect seasonal estimates.

During the reporting period, carcass persistence was influenced by carcass size and Project component. Small carcasses (0-100 g) in the arrays and along the fence (combined) had a 0.54 probability (90% confidence interval [CI]: 0.47 – 0.61) of persisting through the 7-day search interval, medium carcasses (101 – 999 g) had a 0.82 (0.69 – 0.92) probability, and large carcasses (1000+ g) had a 0.94 (0.88 – 0.98) probability. Mean removal time within the arrays for small, medium, and large carcasses was 5.7, 29.8, and 126.8 days, respectively. Along the generation tie-line, probability of persistence for small, medium, and large carcasses were 0.29 (0.19-0.39), 0.71 (0.52-0.85), and 0.72 (0.53-0.85), respectively; mean removal time for small, medium, and large carcasses was 2.0, 13.7, and 14.7 days, respectively. Within the solar arrays, searcher efficiency was influenced by carcass size: 60.0% for small birds, 87.2% for medium birds, and 97.3% for large birds. Along the fence, searcher efficiency ranged from 79.3% to 100% depending on carcass size class. Along the generation tie-line, searcher efficiency ranged from 53.9% to 87.8%.

Using the Huso (2010) fatality estimator model, during the spring period 2015, there were an estimated total 111 fatalities (90% CI: 58 - 193) at the Project. Of these, 49 fatalities (44.1%; 90% CI: 19 – 86) were estimated for the solar arrays, 2 fatalities (1.8%; 90% CI: 2 – 4) were estimated for the fence, and 60 fatalities (54.1%; 90% CI: 16 – 132) were estimated for the gen-tie line.There were an estimated 0.02 carcasses per acre (49 estimated carcasses/2,585 acres) and an estimated 0.09 carcasses per nameplate MW (49 estimated carcasses/ 550 MW) within the solar field. All of these estimates should be interpreted with caution because the variance estimates are in general unreliable when carcass counts are low (< 5 per category). Other projects (e.g. Ivanpah) are not reporting estimates when carcass counts are < 5 in a category, but the TAG has requested them for this project.

1.0 INTRODUCTION

1.1 Project Background

Desert Sunlight 250, LLC and Desert Sunlight 300, LLC (collectively, Desert Sunlight) constructed and operates the Desert Sunlight Solar Farm Project (referred to in this report as "Project"), which consists of two main components: 1) a 550-megawatt (MW) photovoltaic (PV) generating facility; and 2) a 220-kilovolt (kV) generation interconnection (gen-tie) line. The Project comprises approximately 1,700 hectares (ha; 4,200 acres) of land administered by the Bureau of Land Management (BLM) six miles north of Desert Center in Riverside County, California (Figure 1).

1.2 Monitoring Plan Overview and Goals

A Bird and Bat Conservation Strategy (2014; “BBCS”) was prepared by the Project proponent in collaboration with the U.S. Fish and Wildlife Service (USFWS), California Department of Fish and Wildlife (CDFW), (BLM) to guide comprehensive monitoring of impacts to birds and bats associated with operation of the Project. Final agency approval of the BBCS occurred in December 2014. Amendments to the sampling protocol along some portions of the Project fenceline were made by Desert Sunlight and approved by the BLM on February 11, 2015.

The BBCS details post-construction monitoring to be conducted and the data analysis and reporting processes that will be implemented by Desert Sunlight in collaboration with the USFWS, CDFW, and BLM. As identified in the BBCS, they are:

1. Estimate overall annual avian fatality rate and species composition associated with the Project infrastructure. This estimate will include mortality associated with solar arrays, overhead lines including the gen-tie line, perimeter fence and other features of the Project that may result in injury and fatality.
2. Determine whether there are spatial and temporal/seasonal patterns of mortality associated with project infrastructure (e.g., different fatality rates near panels on the edge of the arrays vs. the interior area of the arrays).
3. Provide information that will assist the BLM in consultation with the USFWS in understanding which species and potentially which regional populations are at risk.
4. Collect data in such a way that the BLM in consultation with the USFWS may make comparisons with other solar sites.

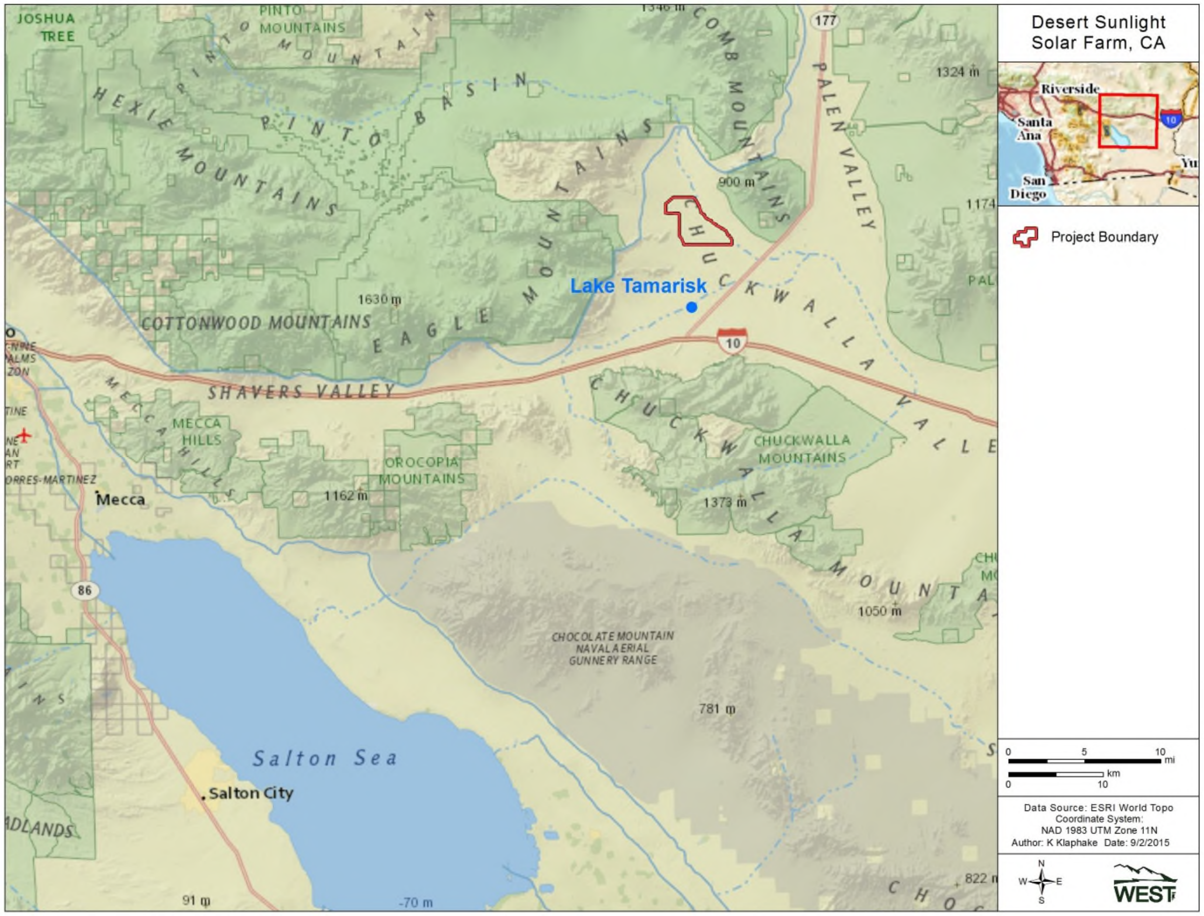

Figure 1. Desert Sunlight Solar Farm Project vicinity map, Riverside County, California.

1.3 Purpose of This Report

This report represents the first seasonal report for the first year of monitoring summarizing monitoring methods and results for avian and bat fatalities and injuries based on the procedures and requirements specified in the approved BBCS. This report covers the period February 10 to February 28, 2015, as well as the 2015 spring season, which includes the period from March 01 to May 31, 2015. All bird and bat fatalities and injuries that were discovered by observers are referred to as “detections” in this report. Per USFWS comments on an earlier draft of this report (dated July 17, 2015), carcass search data collected before March 01 have been excluded and are not reported here. As stated in the approved BBCS, this seasonal report includes the observed detections for likely diurnal, and likely nocturnal species, and for ecological guilds of interest (e.g., raptors, water-associated birds, passerines), for each of the facility types and suspected causes of death. Species composition of detections and the results of the bias trials are also reported. This report presents information related to the spatial distribution of detections, but no formal statistical analysis of the spatial distribution of carcasses will be conducted until the end of the monitoring year, given the limited data presently available.

2.0 METHODS

The BBCS describes the methods by which monitoring and certain analyses, including compilation of the overall fatality estimate, will occur. Below is an abridged description (see BBCS for detailed methods).

2.1 Standardized Carcass Searches

This section describes areas surveyed, the timing and frequency of searches, and the methods by which standardized searches were conducted to identify dead/injured birds and bats at the Project. Dead or injured birds and bats are called detections in this report to provide consistency in naming. This section also describes the methods for conducting carcass removal and searcher efficiency trials; how data were reported and analyzed; and the methods for producing fatality estimates for the Project.

2.1.1 *Areas Surveyed*

Standardized carcass searches were conducted at sampling units, which include the solar arrays (Table 1, 2; Figure 2); the “fenceline” defined as the perimeter fence for the Project (Table 1, Figure 2); and the gen-tie line (from the Project fence to the Red Bluff Substation on the south side of I-10; Table 1, Figure 3). Some overhead lines co-occur with solar arrays (medium voltage overhead lines [MVOH]). The MVOH were part of standardized carcass searches to the extent that they co-occured with solar arrays included in the sample (Table 3; Figure 2).

Table 1. Areas included in standardized carcass searches at the Desert Sunlight Solar Farm Project during spring 2015.

Project Component	Total Size	Units	% of Component Searched
Solar arrays	1045.9	Hectares	28.2[1]
Solar arrays	1045.9	Hectares	1.3[2]
Solar arrays	1045.9	Hectares	1.3[3]
Fence	16.7	Kilometers	99%[4]
Gen-tie line	19.2	Kilometers	47.9[5]

[1] Percent area that was searched continuously since monitoring commenced in February 2015. Slightly less than 30% total (including areas affected by the tornado) because of unequal size arrays.

[2] Percent that was searched before the April 21, 2015 tornado but not after.

[3] Percent that was searched after the tornado but not before.

[4] 74.4% of the fence is fully accessible and surveyed following the standard protocol, while approximately 25% of the fence is surveyed from a distance. Fatality rates estimated for sections of the fence that are sampled were extrapolated to sections of the fence where the standard monitoring protocol cannot be used, as described in section 4.2.6 of the approved Desert Sunlight BBCS. A very short segment near the gate is not sampled due to restoration activities.

[5] 52.1% of gen-tie will be sampled in 2016.

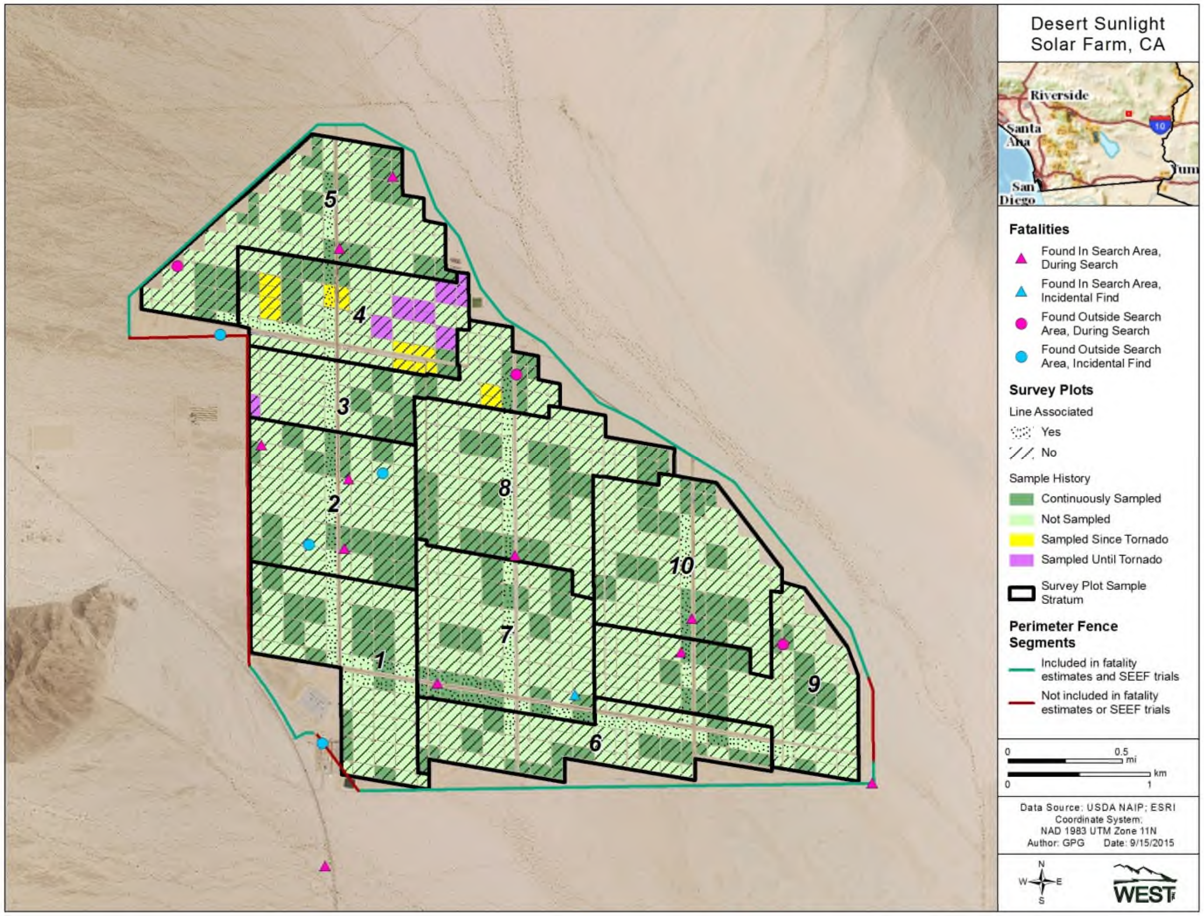

Figure 2. Areas of standardized searches and detections (those made during searches and those made incidental to operations and maintenance) at the solar field, fence, and overhead lines within the fence at Desert Sunlight Solar Farm Project during spring 2015.

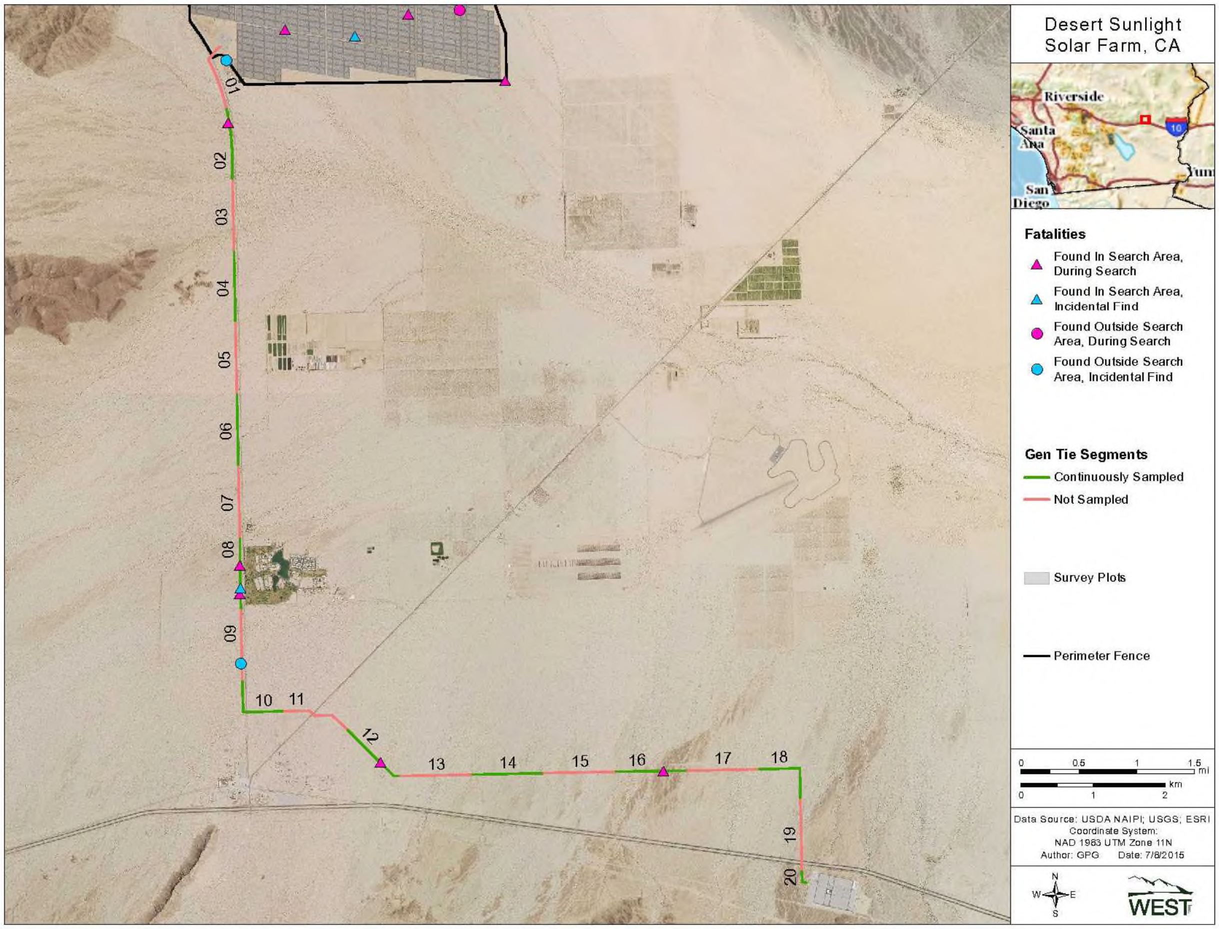

Figure 3. Areas of standardized searches and detections (those made during searches and those made incidental to operations and maintenance activities) along the generation tie line at the Desert Sunlight Solar Farm Project during spring 2015. Detailed maps of detections along the line are presented in Appendix A.

To ensure a balanced distribution of sample units in the solar field (defined as the collection of all photovoltaic [PV] solar panels), the entire field was divided into ten strata, and individual sampling units were randomly selected within each stratum to compose an approximately 30% sample. The solar field consists of arrays of solar panels (referred to as a solar array). This sampling design ensures that units included in the sample were not spatially clumped within the solar field.

2.1.2 *Search Frequency and Timing*

Standardized searches occurred during the spring survey season, which includes the period from March 01 through May 31, 2015. All project components included in standardized searches were surveyed 12 times during spring. All searches took place during daylight hours from 06:30 to 17:00.

Table 2. Sample sizes and number of rows for each 70-m and 140-m array type included in standardized carcass searches at the Desert Sunlight Solar Farm Project during spring 2015.

	Number of rows		Number of arrays	
Time period	**70 m**	**140 m**	**70 m**	**140 m**
Before tornado	2560	3920	133	133
3-week interim	2460	3720	127	127
After tornado	2580	3900	133	133

As specified in the approved Desert Sunlight BBCS, the average search interval for all Project components included in standardized carcass searches during spring was 7.1 days (median 7 days). Slight variation in search interval was anticipated due to weather and logistical delays. On April 21, 2015, the Project was struck by a tornado. The tornado damaged some of the sampling units, and resulted in limited access that ultimately lasted longer than initially expected. Thus, 142 sample units (128 arrays, fence, and gen-tie combined) were visited 12 times continuously and without interruption during the spring season. Six arrays were visited seven times from the beginning of the spring season until the tornado occurred on April 21, 2015; 3 weeks elapsed before the six damaged arrays were replaced with arrays in the solar field that were not affected by the tornado. During this 3-week period, Desert Sunlight LLC remained in contact with the BLM as details on access limitation developed. Once it was determined that access to damaged arrays would be limited for a longer time period, six replacement arrays were identified; five were visited twice and one was visited once. Replacement arrays were identified by choosing a random sample of non-damaged arrays within the same block that contained the original arrays that were damaged by the tornado.

Table 3. Area, proportion, and detections for solar arrays that are and are not associated with overhead lines at the Desert Sunlight Solar Farm Project.

	Line-associated[1]	**Not line-associated**	**Proportion line-associated**
Entire facility	89.4 ha	956.5 ha	0.09
Standardized searches	32.2 ha	291.0 ha	0.10
Detections	3[2]	10	0.23

[1] Line-associated area was estimated as the area of any array that fell within the 30-m strip transect below the MVOH.

[2] Includes detections where closest component was an MVOH or a line-associated array.

2.1.3 *Search Methods*

Standardized carcass searches were performed by BLM-approved biologists, in accordance with methods outlined in the BBCS.

Within the solar field, arrays of solar panels were surveyed by observers traveling on foot. A distance sampling approach was used, whereby biologists slowly walked a transect line along the ends of rows of solar panels in a direction perpendicular to the rows, searching ahead and to the side within the array for bird and bat detections. Biologists scanned out to a maximum perpendicular distance of approximately 70 m from the transect. Biologists carried binoculars to allow them to verify the presence of a detection versus rocks or vegetation. Once a detection was confirmed, the distance of the detection to the transect line was estimated using laser range finders. Each array included in the sample was searched by observers walking two transects – one on the west side and one on the east side of the array with observers looking toward the center of the array.

Once a carcass was detected, it was then photographed, and data were recorded according to specifications outlined in section 7.2.5 of the approved Desert Sunlight BBCS. Carcasses detected before amendment of the WEST California Scientific Collecting Permit (Permit # 3790) were covered and secured in place until permission was granted from California Department of Fish and Wildlife to handle carcasses on April 21, 2015. Since that date, all carcasses have been retrieved from their location on the ground, labeled, and placed in a freezer on site.

Most (74.4%) of the length of fenceline (approximately 10 miles) was searched from a vehicle using the standard protocol (Figure 2). Biologists searched a 6-m wide strip transect centered on the fence from the inner perimeter. Travel speed was below five miles per hour (mph) while searching. Some sections along the fence cannot be driven close to the fence line. The fence line along the western edge of the Project is drivable but the road is approximately 15 m away from the fence and the road and fence are separated by a drainage ditch. The fence along this section is covered with a tan tarp to block and trees and shrubs have been planted to reduce visibility of the project from the west. Additions of vegetation and the tarp likely reduce potential for bird collision with the fence. This section of the fence was driven to document carcasses, but detections along this portion of the fence are not included in adjusted fatality estimates because detection rates are likely very low. As specified in section 4.2.6 in the approved Desert Sunlight BBCS, we assume that fatality rates are similar between the portion of fence that was searched and the portion that was not. A separate section of the fence in the southeastern corner of the Project cannot be driven because the eastern edge of the berm that bounded construction ponds is too narrow for a vehicle. Along this portion of the fence, the observer stopped at both north and south ends of the berm and used binoculars to search for carcasses. Finally, the road along a portion of the southwest fence line near the entrance gate is approximately 30 to 50 m from the road and is separated from the fence by an area that has recently undergone vegetation restoration. This area was eliminated from sampling. Fatality rates estimated for sections of the fence that were sampled were adjusted to account for the proportion of fence not sampled with the standard monitoring protocol, as specified in section 4.2.6 of the approved Desert Sunlight BBCS.

The gen-tie line was searched using a 30-m wide strip transect (i.e., 15 m of ground on either side of the overhead line). Sample units along the gen-tie line were chosen by dividing the total length of line from the Project fence south to the Red Bluff Substation just south of I-10 into 1-km segments. Thus, a 47.9% sample of the total length of the line was searched (Figure 3). Biologists slowly walked every other 1-km segment of the line, meandering the width of the strip transect, scanning for dead or injured birds or bats within 15 m (49.2 ft) of the overhead line.

For each detection, a suspected cause of death or injury was assigned based on evidence available from the detection, evidence available on Project infrastructure, and proximity of the detection to Project infrastructure. Detections that had evidence of scavenging and lacked evidence on Project infrastructure were assigned as “unknown” because it cannot be determined whether the event was caused by predation or interaction with project infrastructure. Detections that were intact (i.e., no evidence of scavenging) and located in close proximity to Project infrastructure (e.g., found directly beneath overhead lines) had a suspected cause of death attributed to the respective Project component. However, it should be noted that there is substantial uncertainty associated with cause of death assignments because no events were directly observed. Detections assigned to the “unknown” category were included in fatality estimates if they were located within standardized carcass search areas.

2.2 Carcass Persistence Trials

Carcass persistence trials were conducted during February and throughout the spring period. Carcasses from three size classes (small [0-100 g], medium [101-999], and large [1000+ g]) were used for trials. The small size class comprised house sparrows (*Passer domesticus*) and 2-3 week old coturnix quail (*Coturnix coturnix*), the medium size class comprised rock pigeons (*Columba livia*), and the large size class comprised hen mallard (*Anas platyrhynchos*) and hen ring-necked pheasant (*Phasianus colchicus*).

2.2.1 *Carcass Persistence Data Collection*

To quantify carcass persistence rates, 15 small, 10 medium, and 5 large carcasses (i.e., trials) were randomly placed and monitored along the gen-tie line during spring 2015. Within the solar arrays and along the perimeter fence, the same numbers of small and medium carcasses were placed, along with 10 large carcasses, for a total of 65 carcass persistence trials at Desert Sunlight during the spring season, as specified in the approved Desert Sunlight BBCS. By placing carcasses inside and outside the project fence, the possibility that there are different carcass persistence rates inside and outside the project fence is accounted for. As approved by BLM on March 18, 2015, carcass persistence trials within the Project fence were coordinated with trials implemented as part of the Raven Management Plan by Corvus Ecological Consulting, LLC. Thirty-five carcasses within the Project fence (within solar arrays and along the fence) were monitored using motion-triggered digital trail cameras, while the remaining carcasses were visited on foot, for 30 days or until the carcass had deteriorated to a condition at which it would no longer qualify as a documentable fatality. No carcasses along the gen-tie line were monitored with cameras because of theft and vandalism concerns. Carcasses without trail cameras were visited and photographed once per day for the first four days, and then every three to five days until the end of the monitoring period. To avoid training scavengers to recognize cameras as “feeding stations”, trail cameras were installed five days before specimens were placed, and two fake cameras without bias trial carcasses were also placed within the Project fence and periodically moved to new locations within the fence. Periodic ground-based checking of carcasses with trail cameras also occurred to guard against misleading indicators of carcass removal, such as wind blowing the carcass out of the camera’s field of view. To minimize potential bias caused by scavenger swamping (Smallwood 2007, Smallwood et al. 2010), carcass-persistence specimens were distributed across the entire

Project, not just in areas subject to standard searches, and trials were initiated in small numbers on six different dates throughout the spring season.

In February, 15 (*n* = 7 small, 5 medium, and 3 large) carcass persistence trials were placed in the solar arrays and along the Project fence, and 15 trials (*n* = 8 small, 5 medium, and 2 large) were placed along the gen-tie line. Eight carcasses within the arrays and fence were monitored with trial cameras, and four fake cameras were placed within the arrays and along the fence. Carcass persistence trials within the solar arrays and fence were initiated two days earlier in February than trials along the gen-tie line.

2.2.2 *Estimating Carcass Persistence Times*

Measurements of carcass persistence rates were subject to censoring. In this context, censoring refers to the instance when a value (e.g. days a carcass is present before being removed) may not be known exactly, but is known to be within a finite range. For example, suppose a carcass was checked on day 7 and was present, and was checked again on day 10, but was found to be missing. The exact time until removal is unknown; however, it is known that the carcass became unavailable at some point between 7 and 10 days. This carcass would be considered "interval censored". Similarly, if a carcass lasts the entire 30-day trial period, that carcass is "right censored"— it is known that the carcass lasted at least 30 days, but it may have persisted longer. Because carcass persistence data were censored, persistence was analyzed using methods that can accommodate censored data and still produce unbiased estimates of the probability of persistence (Therneau 2015, Therneau and Grambsch 2000).

USGS-developed fatality estimator software (Huso et al 2012) was used to fit survival models to the censored carcass persistence data. There were four distributions implemented in survival models used to estimate the probability a carcass is unscavenged and available to be found at the end of the search interval (*r*): exponential, Weibull, loglogistic, and lognormal. These four distributions exhibit varying degrees of flexibility in order to model a wide variety of distributions of persistence time. Akaike's Information Criterion adjusted for sample size (AICc; Akaike 1973) was used to rank the fit of each survival model with combinations of the covariates carcass size, location, and visibility, to observed carcass persistence data.

2.3 Searcher Efficiency Trials

Searcher efficiency trials were conducted in February and throughout the spring period). Carcasses from three size classes (small, medium, and large) were used for trials. The small size class comprised house sparrows and 2-3 week old coturnix quail (*Coturnix coturnix*), the medium size class comprised rock pigeons, and the large size class comprised hen mallards and hen ring-necked pheasants.

2.3.1 *Searcher Efficiency Data Collection*

Training of biologists on the Project-specific protocol and early assessments of habitat conditions at the Project site suggested that the amount of cobble present in the soil may be an important factor influencing searcher efficiency. To satisfy requirements regarding consideration of visibility class per the BBCS and address the influence of cobble cover on searcher efficiency, sample units in the solar arrays and along the gen-tie were stratified by cobble cover and assigned to one of two classes (<15% and >15% cobble cover). Classes were determined by making ocular estimates of cobble cover at each sample unit and then evaluating the frequency histogram of sample units across the range of estimated cobble cover (Figure 4). A natural break point was identified at 15% cobble cover, so the same value was chosen as the break point that defined the two strata. In the solar arrays, one set of searcher efficiency trials (*n* = 15 small birds, 10 medium birds, and 5 large birds as agreed upon in section 7.4 of the approved Desert Sunlight BBCS) was conducted in each strata. Similarly, searcher efficiency trials along the gen-tie occurred in two visibility strata (easy: ≥90% bare ground, vegetation <6" tall; and more difficult: <90% bare ground, vegetation ≥6" tall). Thirty searcher efficiency trials (*n* = 15 small birds, 10 medium birds, and 5 large birds) occurred along the fence in the only stratum present on the fence (easy visibility). Thus, in February, a total of 150 searcher efficiency trials occurred at the Project, and the same methods and number occurred during the spring season. Locations for trials were chosen by taking a randomized sample of all locations included in standardized carcass searches.

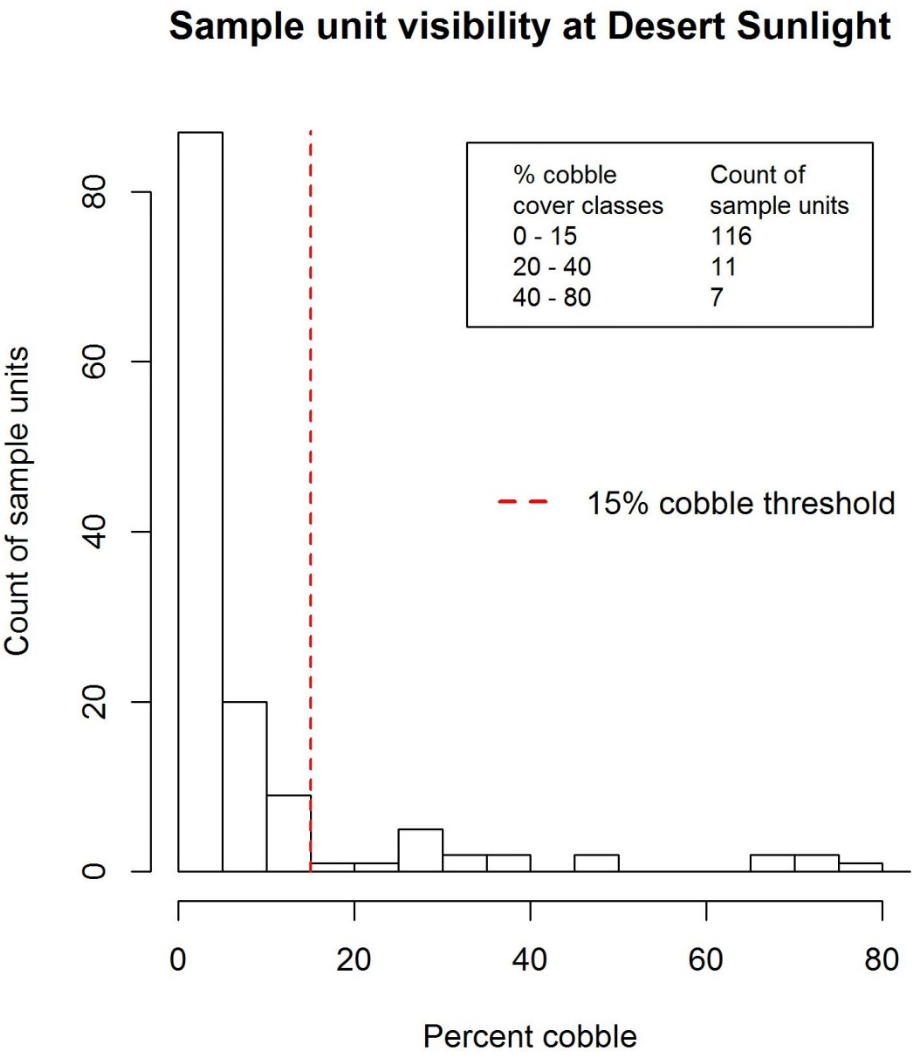

Figure 4. Frequency histogram of sample units (in the arrays only) at Desert Sunlight Solar Farm Project by estimates of cobble cover. Based on this distribution, each sample unit was assigned to one of two classes of cobble cover (<15%; >15%).

2.3.2 *Estimating Searcher Efficiency*

Searcher efficiency at Desert Sunlight was estimated separately for linear features (the project fence and the generation tie line), and the solar arrays, reflecting the different search methods used on arrays and linear features. For linear features, logistic regression models were fit to searcher efficiency data and AICc was used to compare models. Models including effects of carcass size (three classes) and visibility (two classes; gen-tie only), were compared to each other and the null model. Model selection indicated that best models accounted for component, carcass size, and on the gen-tie line, visibility. Once the best model was chosen and appropriate classes identified, searcher efficiency, or the proportion of carcasses detected, p, was calculated for each class using the following equation:

$$p = \frac{Number\ of\ Carcasses\ Observed}{Number\ of\ Carcasses\ Available}$$

The data for this analysis included all searcher efficiency trial carcasses from February and the spring 2015 season.

For the solar arrays, searcher efficiency was evaluated using a distance sampling approach (Buckland et al. 1993). Distance sampling assumes perfect detection on the transect line (at distance = 0), an assumption that is likely valid in the solar arrays given the relatively flat & vegetation-free nature of the soil surface. A curve is fitted to the observed carcass data that predicts probability of detection as a function of distance from the transect line. The mean value of this function over a specified distance, *w,* is equal to the average searcher efficiency for atransect of width *w*. The mean value of the detection curve is the integral of the detection function calculated between 0-m and the maximum survey distance (*w;* half the width of the solar array row), divided by the maximum survey distance:

$$p = \frac{\int_0^w f(x)dx}{w},$$

where f(x) is the detection function evaluated at distance, *x*.

One departure in the methods used here, relative to the methods presented in Buckland et al. (1993), was that for this study the detection function was estimated using trial carcasses, which meant that there were both presence (detected) and absence (not detected) data available to fit the detection function (Figure 5). The availability of both presence and absence data means that the detection function can be estimated using only trial carcasses whose distribution is known. Therefore the detection function, the average searcher efficiency among the arrays and the final fatality estimate within the arrays are all insensitive to the spatial distribution of carcasses within individual arrays, and the overall searcher efficiency estimate is valid even if the distribution of carcasses among the arrays is not uniform.

Distances of trial carcasses (trials both found and missed) from the transect line were used to fit a half-normal detection function for searches among the arrays (Figure 5). The half-normal detection function is a commonly used function for distance sampling surveys (Buckland et al. 1993). The detection function was fit with and without covariates (carcass size, visibility index, or no covariates) and AICc indicated that the best among these models included only carcass size as a covariate.

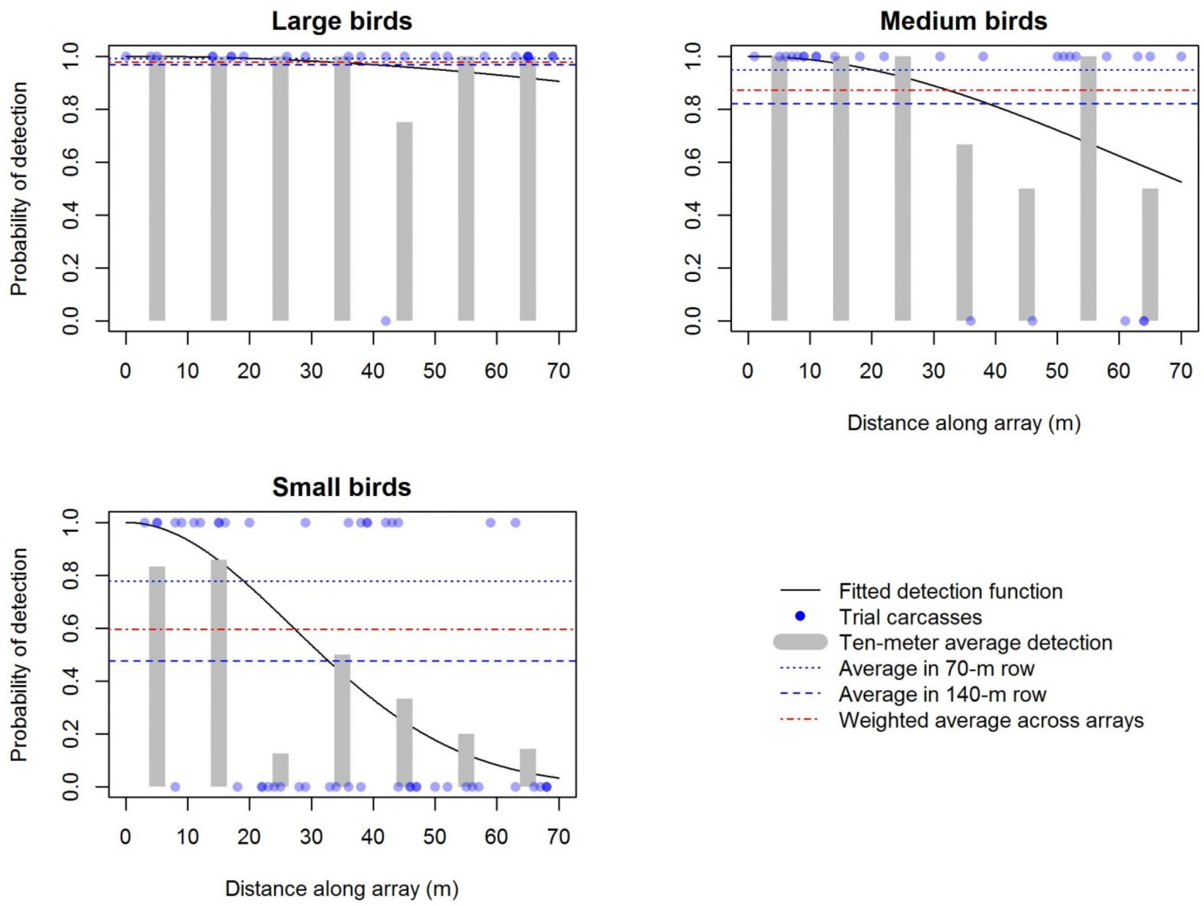

Figure 5. Estimated detection probabilities for bird carcasses by size class during spring 2015 (including February) at the Desert Sunlight Solar Farm Project, Riverside County, California. Distance sampling was used when searching solar arrays only. Average probability of detection over 70-m (arrays relying on a 35-m viewshed) and 140-m (arrays relying on a 70-m viewshed) panel rows in solar arrays are presented.

Because the solar arrays were surveyed by searchers who walked down both sides of the rows of panels, the width of the search transect was specified as half the width of the rows of panels. For larger birds, there is almost certainly a non-zero detection probability beyond this distance but the bias that occurs by ignoring this non-zero detection probability is conservative (i.e. the searcher efficiency is underestimated). Some solar arrays have row widths of 70 m (search transect width of 35 m) and some have row widths of 140 m (search transect width of 70 m). The weighted average searcher efficiency is calculated based on the number of panel rows of each length in the survey sample:

$$p_{weighted\ average} = \frac{n_{70}}{n} \times \int_0^{35} f(x)dx + \frac{n_{140}}{n} \times \int_0^{70} f(x)dx,$$

where n_{70} is the number of 70-m rows in the sample, n_{140} is the number of 140-m rows in the sample, and *n* is the total number of rows in the sample.

Searcher efficiency was higher for the arrays with a width of 70 m, and overall searcher efficiency was estimated as a weighted average based on the proportions of 70-m arrays and 140-m arrays in the sample units.

2.4 Fatality Estimator

Fatality rate estimation is a complex task due to several variables inherent to every fatality monitoring study. Carcasses may persist for variable amounts of time due to local scavenger activity or environmental conditions leading to carcass degradation over time. Carcasses and feather spots are also detected with varying levels of success based on carcass characteristics and ground cover (e.g., vegetated areas underneath the gen-tie line versus cleared areas beneath solar panels). For these reasons, it is generally inappropriate to draw conclusions based on the raw number of fatalities alone. The desire to estimate fatalities given these variables has driven the development of several statistical methods for estimating fatalities (e.g., Smallwood 2007, Huso 2010, Korner-Nievergelt 2011). All of these fatality estimation methods share a similar underlying model. Generally, the fatality estimation for a given site may be written as:

$$F=C/rp,$$

where F is the total number of fatalities, C is the number fatalities detected and included in fatality estimation, r is the probability a carcass is unscavenged and available to be found at the end of the search interval, and p is the probability of detecting a carcass (Huso 2010).

All fatality estimates were calculated using the Huso estimator, as well as 90% confidence using bootstrapping (Manly 1997). Bootstrapping is a computer simulation technique that is useful for calculating point estimates, variances, and confidence intervals for complicated test statistics. A total of 1,000 bootstrap replicates were used. The lower 5th and upper 95th percentiles of the 1,000 bootstrap estimates provide estimates of the lower limit and upper limit of an approximate 90% confidence interval on all estimates.

2.5 Incidental Reporting

Some detections were outside standardized search areas, or were within search areas but not observed during standardized searches. Such detections were found by WEST avian biologists and operational personnel and were considered “incidental” detections. When found by operational personnel, these detections were reported to WEST avian biologists for documentation. Data on incidental detections are reported here, as well as in the Desert Sunlight SPUT Avian Injury and Mortality Report Forms March – May 2015. All detections made in search areas during the reporting period were included in fatality estimates, regardless of whether they were detected incidentally or during searches.

3.0 MONITORING RESULTS

3.1 Summary of Avian Detections

During spring 2015, a total of 23 avian detections (including one injured bird and incidentals) of 12 identified species were recorded (Table 4). The most numerous detection of an identified species was common loon (*Gavia immer*) with four detections. Most detections (n = 10, or 43.5% of total detections) occurred in the solar arrays (Figures 2 and 3; Tables 4, 5, and 6). Seventeen (73.9%) detections were made during standardized carcass searches and six (26.1%) were documented as incidentals. For fresh carcasses, body weights and weather conditions the preceding nights are described in Appendix B.

Table 4. Number of individual bird detections, by species, during spring 2015 at the Desert Sunlight Solar Farm Project, Riverside County, California. NLA = non-line associated solar array; LA = line-associated solar array.

Table 4. Number of individual bird detections, by species, during spring 2015 at the Desert Sunlight Solar Farm Project, Riverside County, California. NLA = non-line associated solar array; LA = line-associated solar array.

Common Name	Scientific Name	Migration Behavior*	Guild	Count	Project Component
				1	gen-tie line
				1	LA solar array
Wilson's warbler	*Cardellina pusilla*	nocturnal	warblers	1	gen-tie line
Total				**23**	

* See literature cited for migration behavior references; information for most species was taken from the respective species accounts found in Birds of North America (BNA) Online (http://bna.birds.cornell.edu/bna/); where information on migration behavior was lacking in BNA accounts, Newton (2008) or Murray (2004) were used.

Table 5. Total avian detections by Project component and detection category during spring 2015 at the Desert Sunlight Solar Farm Project, Riverside County, California. Only carcasses found within search areas were included in fatality estimates.

	Inside carcass search area		Outside carcass search area	
Project Component	**Carcass search**	**Incidental**	**Carcass search**	**Incidental**
Fence	1	0	0	1
O&M Building	0	0	0	1
Gen-tie line	3	1	0	1
Solar arrays				
Line-associated	3	0	0	0
Non-line associated	7	0	3	2

Table 6. Total avian detections (including incidentals) by Project component and suspected cause of death during spring 2015 at the Desert Sunlight Solar Farm Project, Riverside County, California.

	Suspected Cause of Death*				
Project Component	**Collision**	**Predation**	**Other**	**Unknown**	**Percent of Total**
Fence	1	0	0	1	8.7
O&M building	0	0	1	0	4.3
Gen-tie line	5	0	0	0	21.7
Solar arrays					
Line-associated	2	0	0	1	13.0
Non-line associated	1	1	5	5	52.2
Percent of Total	**39.1**	**4.3**	**26.1**	**30.4**	**100.0**

* Suspected cause of death was assigned based on evidence available on the detection, evidence available on Project infrastructure, and proximity of detection to Project infrastructure. Detections that had evidence of scavenging and lacked evidence on Project infrastructure were assigned as "unknown" because it cannot be determined whether the event was caused by predation or interaction with project infrastructure. Detections that were intact (i.e., no evidence of scavenging) and located in close proximity to Project infrastructure (e.g., found directly beneath overhead lines) had a suspected cause of death attributed to the respective Project component. However there is some uncertainy associated with cause of death assignments because no events were directly observed.

3.2 Temporal Patterns of Avian Detections

The number of detections recorded daily during the reporting period ranged from zero to two (Figure 6). The period from March 30 to May 27 was characterized by slightly higher numbers of detections with more days with two detections than the previous period. The number of detections per day represents those discovered during standardized carcass searches and incidentally.

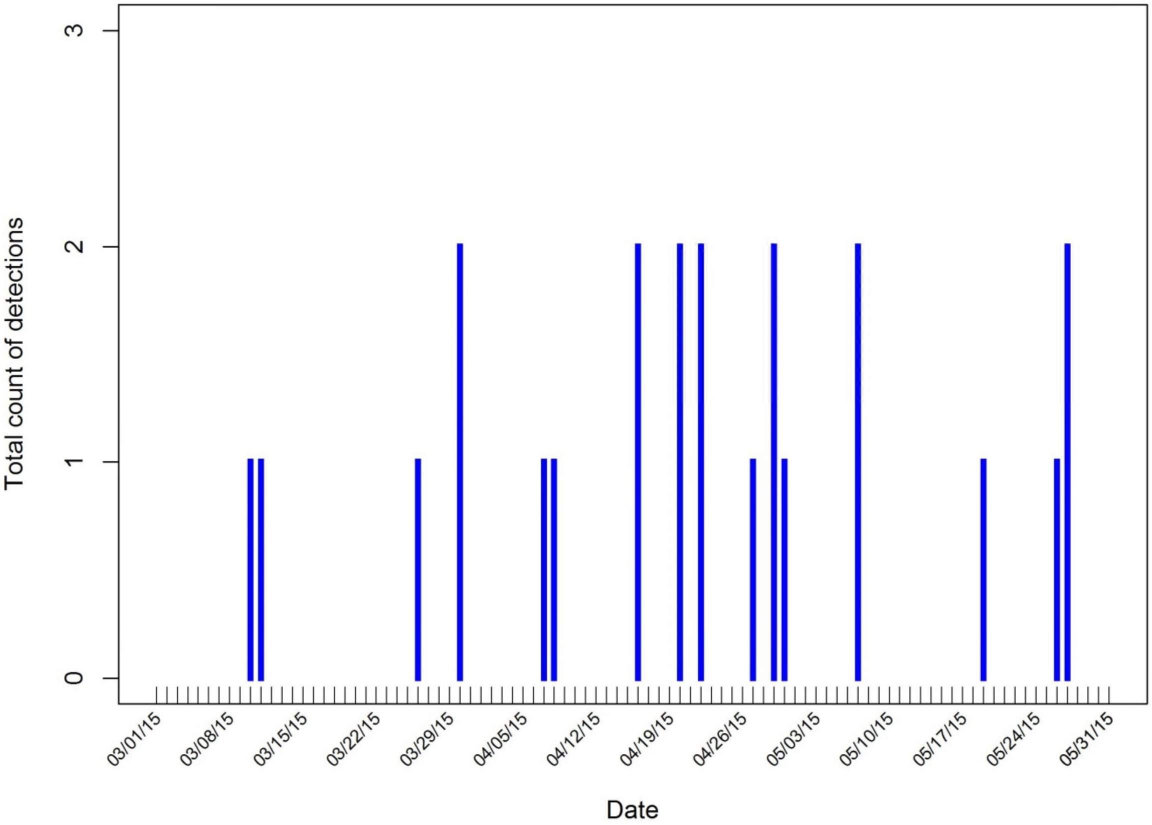

Figure 6. Total number of detections by date during spring 2015 at the Desert Sunlight Solar Farm Project, Riverside County, California.

3.3 Spatial Distribution of Avian Detections

3.3.1 *Detections by Project Component*

During the reporting period, detections were documented from the solar arrays, perimeter fence, gen-tie line, MVOH lines within the solar field, and the O&M building (Tables 3, 4, 5 and 6). Of the 10 detections within the solar arrays, half (5) were assigned to the “unknown” category for suspected cause of death.

3.3.2 *Feather Spot Detections*

Seven (30.4.0%) of the 23 detections consisted only of feather spots. Along the fence, one detection (4.3%) was a feather spot. Two detections (8.7%) along the gen-tie line were feather spots. Four detections (17.4%) in the solar arrays were feather spots.

3.4 Detections of Injured Birds

One bird was located during the reporting period that was injured. A mourning dove (*Zenaida macroura*) was discovered on April 22 along the northern section of the perimeter fence. The bird had an obvious injury to its breast. Because the bird was found the day after the tornado struck the Project, the injury may have been a result of the storm. The bird was taken to Coachella Valley Wild Bird Center and left with Linda York for rehabilitation. Numerous attempts to determine the final outcome for the dove were unsuccessful. The single injured bird detection was included in the fatality estimates.

3.5 Summary of Bat Detections

No bats were located during the spring 2015 season.

3.6 Carcass Persistence Trials

Based on carcass persistence data from the spring 2015 season (and including February), 20 survival models were compared for relative quality using the corrected AICc score, as suggested in Huso (2010). The AICc score provides a relative measure of model fit and parsimony among a selection of candidate models, and provides a framework for testing hypotheses regarding which factors contribute to carcass persistence rates. Carcass size was tested as a potentially important variable, as larger carcasses tend to persist longer and may be more likely to leave feather spots which persist for long durations, whereas smaller carcasses may be more likely to be completely removed. Project component (solar arrays/fence, generation-tie line) was also included as a potentially important variable, as was season (February, or March-May).

The model with lowest AICc score is typically chosen as the “best” model relative to other models tested; however, any model within two AICc points of the best model is considered competitive with the best model (Burnham and Anderson 2004). The best model had a ΔAICc value of 0.77 and included effects of carcass size (small, medium or large), and location (solar arrays/fence or generation-tie line) with a Weibull-distributed removal time, but no effect of season. Estimates from the best model of carcass removal time and persistence probabilities are reported in Table 5 and Appendix C, and Figure 7 provides estimates of proportion of carcasses remaining as a function of days since carcass placement.

Table 7. Mean carcass removal time and probability of a carcass persisting through the 7-day search interval during the reporting period at the Desert Sunlight Solar Farm Project, Riverside County, California.

Carcass size	Project component	Mean removal time (days)	Probability of persistence
Small	Arrays/fence	5.7	0.54
Small	Overhead lines	2.0	0.29
Medium	Arrays/fence	29.8	0.82
Medium	Overhead lines	13.7	0.71
Large	Arrays/fence	126.8	0.94
Large	Overhead lines	14.6	0.72

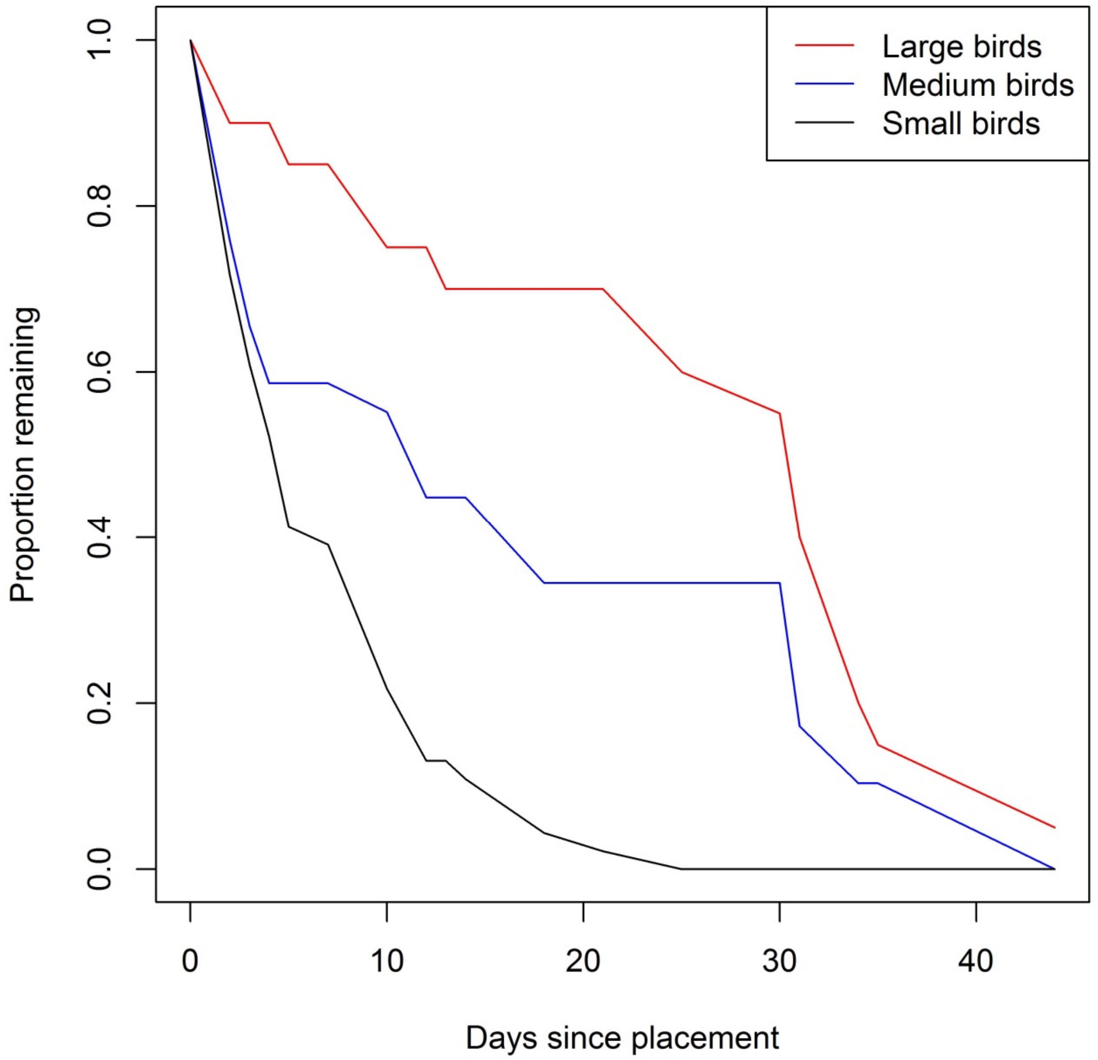

Figure 7. Proportion of trial carcasses remaining as a function of days since placement and carcass size class (n = 46, 29, and 20 for small, medium, and large size classes, respectively) February – May 2015 at the Desert Sunlight Solar Farm Project, Riverside County, California.

3.7 Searcher Efficiency Trials

During the reporting period, a total of 300 searcher efficiency trials were placed at the Project. Most trials were available to be found, but some disappeared before or during the trial. Overall, 120 trials were placed in the solar arrays and 102 were available to be found; 60 trials were placed along the perimeter fence (inner perimeter only) and 59 were available to be found; and 120 trials were placed along the gen-tie line and 105 were available to be found. Five observers conducted searches at the Project during spring because of personnel turnover. Searcher efficiency trials were conducted on each observer in approximate proportion to the number of searches they conducted at the Project, as follows: Pam Bullard (number of trials available to be found: 8), Anika Mahoney (9), David Gallagher (21), Sarah Nichols (34), and Jennifer Johnson (91). All trials were included in estimation of searcher efficiency.

In the solar arrays, the model that included an effect of carcass size was chosen as the best model to estimate searcher efficiency (Appendix C). Within the solar arrays, searcher efficiency was influenced by carcass size: 60.0% for small birds, 87.2% for medium birds, and 97.3% for large birds (Appendix C). Along the fence, searcher efficiency ranged from 79.3% to 100% depending on carcass size class. Along overhead lines, searcher efficiency ranged from 53.9% to 87.8% (Appendix C). Detailed estimates of searcher efficiency estimates specific to each component and carcass size are reported in Appendix C.

3.8 Fatality Estimates

Fatality estimates were calculated separately for each component (solar arrays, fence, and overhead lines). Ultimately, nine detections were excluded from the fatality analysis: five were found outside standardized search areas; one was estimated to be older than the 7-day search interval (Huso 2010); and three were both outside standard search areas and estimated to be older than the 7-day search interval.

During spring 2015, there were an estimated total 111 fatalities (90% CI: 58 - 193) at the Project (Appendix C). Of these, 49 fatalities (44.1%; 90% CI: 19 – 86) were estimated for the solar arrays, 2 fatalities (1.8%; 90% CI: 2 – 4) were estimated for the fence, and 60 fatalities (54.1%; 90% CI: 16 – 132) were estimated for the gen-tie line (Appendix C). All of these estimates should be interpreted with caution because variance of the estimates are generally unreliable when carcass counts are low (< 5 per category).Other projects (e.g. Ivanpah) are not reporting estimates when carcass counts are low. However, the TAG has asked for both the estimates and confidence intervals for this project with the appropriate caveat added. There were an estimated 0.02 fatalities per acre (within the solar field only) and an estimated 0.20 fatalities per nameplate MW at the Project. A complete list of estimates for each Project component and carcass size class with confidence intervals is presented in Appendix C.

4.0 DISCUSSION

The 2015 spring season represented the first full season of standardized monitoring at Desert Sunlight per the BBCS. Searcher efficiency trials and carcass removal trials were conducted concurrently at the solar arrays, fencelines, and along the gen-tie line. Data from these trials were used to produce fatality estimates adjusted for searcher efficiency and carcass persistence bias. Although these estimates were produced from a statistically robust sample, only limited inference may be drawn from a single season of data. These results should be considered preliminary because estimating carcass persistence, searcher efficiency, and adjusted numbers of fatalities within each season represents information based on a limited sample size. As more data are collected throughout the monitoring year (and additional quality assurance/quality control measures occur, for example characterizing feather spots to species or size class), data from all seasons may be pooled. At that time, data will be tested for seasonal differences retrospectively, but because seasonal estimates will be produced from the much larger annual data set, they may differ from what is reported here because they are based on a larger, more informative sample.

4.1 Carcass Persistence and Searcher Efficiency Trials

The degree to which carcasses persist on the landscape depends on a variety of factors reflecting seasonal and inter-annual variation in habitat, climate, and the scavenger community. The composition and activity patterns of the scavenger community often vary seasonally as birds migrate, new juvenile birds and mammals join the local population, and mammalian scavengers variably hibernate or estivate. The scavenger community may also vary substantially from year to year because of variation in annual reproduction and survival related to changes in landscape condition. Climatic conditions that vary seasonally and annually also may contribute to variation in carcass decay and removal rates due to variation in temperatures, solar insolation, wind patterns, and the frequency of flooding events. Thus, rates of carcass persistence reported here should be interpreted cautiously as they may change over the coming months.

Searcher efficiency was influenced by Project component, carcass size, and visibility class (along the gen-tie only). In the solar arrays, searcher efficiency was high (> 0.5) for all carcass size classes and this is likely influenced by the limited vegetation cover beneath solar panels. Beneath the gen-tie line vegetation cover is higher in some portions of the strip transects, and results reported here support the hypothesis that visibility class is a factor in searcher efficiency along the lines.

For the current analysis, searcher efficiency in the solar arrays was assumed to be best predicted by a half-normal distribution. For future analyses, AICc will be used to compare and choose the best among multiple detection functions.

.

4.2 Distribution of Fatalities and Fatality Estimates

The number of detections was more or less evenly distributed across the spring season, and there were no clear associations between number of detections and date. Given the small number of detections overall, it is premature to draw any conclusions about the spatial distribution of carcasses.

Detections attributed to an unknown cause accounted for 30.4% of all detections during the reporting period, and the distribution of the unknown cause detections varied by project component with 26.1% occurring in association with the solar arrays. Of the 15 detections made in the solar arrays, 26.7% were feather spots. Determining a cause of mortality from a feather spot is challenging because there is rarely visible evidence available on which to determine a cause of death. Thus, feather spots with an unknown cause of mortality could be encountered anywhere birds occur, and an unknown cause of a sizeable proportion of the carcasses is not unique to the Project. Further, the relatively large proportion of feather spots (30.4%) among the detections for the Project as a whole may inflate the fatality estimate when unknown cause detections are included based on the potential for multiple feather spots resulting from one fatality, feather spots resulting from predation not associated with the facility, or other causes.

Draft Pre-Decisional Document – Business Confidential

EXECUTIVE SUMMARY

Avian and bat monitoring surveys were conducted from June 01 to August 30, 2015 (the reporting period) at Desert Sunlight Solar Farm Project (Project) in accordance with the Project's Bird and Bat Conservation Strategy (BBCS). For logistical reasons, fall monitoring began on Monday, August 31, 2015. Specifically, standardized carcass searches, searcher efficiency trials, and carcass persistence trials were conducted. This report represents the second seasonal report for the first year of monitoring, and summarizes monitoring methods and results for those surveys based on the procedures and requirements specified in the BBCS. This report and the other interim quarterly reports are considered preliminary summaries of data and information for the seasonal monitoring periods. Final information from all four quarterly monitoring periods will be included in a comprehensive final annual report.

Included in this report are data from standardized carcass searches conducted during the summer season at the Project, defined as June 01 to August 30, 2015. Standardized carcass searches were conducted 1) in the solar field, consisting of a random stratified 29.5% sample of solar photovoltaic (PV) panels, 2) along inner portions of the fenceline, resulting in 74.4% of the length of the perimeter fence, and 3) along 47.9% of the total length of generation-tie (gen-tie) line from the Project fence to the Red Bluff Substation located south of Interstate 10 (I-10). Searches conducted within the summer season had intervals of approximately 21 days.

All bird and bat fatalities and injuries that were discovered by observers, referred to as "detections" in this report, including those found incidentally and during standardized carcass searches, were documented. During the reporting period, 15 avian detections were made, and there were no detections of bats.

According to specifications of the BBCS, avian detections were categorized by likely diurnal or nocturnal migration behavior, ecological guild (e.g., raptors, songbirds, etc.), facility component, and suspected cause of death. These standardized carcass search results, along with searcher efficiency and carcass persistence rates from bias trials conducted on site, were applied to a fatality estimator model (Huso 2010) to provide a preliminary estimate of the number of fatalities that occurred at the Project during the reporting period adjusted for sources of bias. The estimate is considered preliminary because the annual report may pool information from bias trials and other data across seasons which could affect seasonal estimates.

During the reporting period, carcass persistence was influenced by carcass size and Project component. Small carcasses (0-100 g) in the arrays and along the fence (combined) had a 63% chance (90% confidence interval [CI]: 48 – 76%) of persisting through the effective search interval, medium carcasses (101 – 999 g) had a 73% (55 – 86%) chance, and large carcasses (1000+ g) had a 100% chance because no removal was observed. Mean removal time within the arrays for small and medium carcasses was 15.5, and 19.2 days, respectively; median removal time for small and medium carcasses was 11.5, and 22.5 days, respectively; mean and median removal times were not estimated for large carcasses because no removal was observed. Along the generation tie-line, chances of persistence for small, medium, and large carcasses were 22% (14 – 26%), 60% (37 – 74%), and 22% (14 – 26%), respectively; mean removal time for small, medium, and large carcasses was, 1.4, 14.8, and 0.9 days, respectively; median removal time for small, medium, and large carcasses was, 0.5, 15.8, and 0.5 days respectively. The difference in carcass removal times between Project components is likely because scavengers occur in higher densities outside the perimeter fence.

Within the solar arrays, searcher efficiency averaged over all searchers and seasons (n = 180) was influenced by carcass size: 60.0% for small birds, 86.6% for medium birds, and 98.1% for large birds. Along the fence in summer (n = 30), searcher efficiency ranged from 87.5% to 100% depending on carcass size class. Along the generation tie-line in summer (n = 55), searcher efficiency ranged from 43.5% to 100%.

Composition of detections during summer 2015 included eight avian guilds. Corvids comprised the majority of detections (n = 3): there were two detections each within the doves/pigeons, rails/coots, and waterbirds/waterfowl guilds. No bats have been detected since monitoring began at the Project.

Using the Huso (2010) fatality estimator model, modified to accommodate a distance-sampling approach to the estimation of searcher efficiency, during summer 2015, there were an estimated total 148 carcasses (90% CI: 10 – 365) at the Project. Of these, 44 carcasses (27.5%; 90% CI: 8 – 64) were estimated for the solar arrays and 104 carcasses (66.9%; 90% CI: 2 – 339) were estimated for the gen-tie line. While we are required to report the gen-tie estimates per the approved BBCS, these estimates are not reliable due to the high rates of scavenging that were observed during the limited trials at the gen-tie and the low number of carcasses detected (n = 2 in the fatality analysis). No carcasses were estimated for the perimeter fenceline because there were no detections made along the fence. All of these estimates should be interpreted with caution because variance estimates are in general unreliable when carcass counts are low (< 5 per category). The TAG has asked for both the estimates and confidence intervals for this project with the appropriate caveat added. There were an estimated 0.017 fatalities per acre (within the solar field only; 44 estimated carcasses/2,585 acres) and an estimated 0.08 fatalities per nameplate MW (44 estimated carcasses/550 MW) within the solar field.

1.0 INTRODUCTION

1.1 Project Background

Desert Sunlight 250, LLC and Desert Sunlight 300, LLC (collectively, Desert Sunlight) constructed and operates the Desert Sunlight Solar Farm Project (referred to in this report as "Project"), which consists of two main components: 1) a 550-megawatt (MW) photovoltaic (PV) generating facility; and 2) a 220-kilovolt (kV) generation interconnection (gen-tie) line. The Project comprises approximately 1,700 hectares (ha; 4,200 acres) of land administered by the Bureau of Land Management (BLM) six miles north of Desert Center in Riverside County, California (Figure 1).

1.2 Monitoring Plan Overview and Goals

A Bird and Bat Conservation Strategy (2014; “BBCS”) was prepared by the Project proponent in collaboration with the U.S. Fish and Wildlife Service (USFWS), California Department of Fish and Wildlife (CDFW), and BLM to guide comprehensive monitoring of impacts to birds and bats associated with operation of the Project. Final agency approval of the BBCS occurred in December 2014. Amendments to the sampling protocol along some portions of the Project fenceline were made by Desert Sunlight and approved by the BLM on February 11, 2015.

The BBCS details post-construction monitoring to be conducted and the data analysis and reporting processes that will be implemented by Desert Sunlight in collaboration with the USFWS, CDFW, and BLM. As identified in the BBCS, they are:

1. Estimate overall annual avian fatality rate and species composition associated with the Project infrastructure. This estimate will include mortality associated with solar arrays, overhead lines including the gen-tie line, perimeter fence and other features of the Project that may result in injury and fatality.
2. Determine whether there are spatial and temporal/seasonal patterns of mortality associated with project infrastructure (e.g., different fatality rates near panels on the edge of the arrays vs. the interior area of the arrays).
3. Provide information that will assist the BLM in consultation with the USFWS in understanding which species and potentially which regional populations are at risk.
4. Collect data in such a way that the BLM in consultation with the USFWS may make comparisons with other solar sites.

1.3 Purpose of This Report

This report represents the second seasonal report for the first year of monitoring summarizing monitoring methods and results for avian and bat fatalities and injuries based on the procedures and requirements specified in the approved BBCS. This report and the other interim quarterly reports are considered preliminary summaries of data and information for the seasonal monitoring periods. Final information from all four quarterly monitoring periods will be included in a comprehensive final annual report. This report covers the period June 01 to August 30, 2015, or the 2015 summer season. For logistical reasons, fall monitoring began on Monday, August 31, 2015. All carcasses and injuries that were discovered by observers are referred to as "detections" in this report. As stated in the approved BBCS, this seasonal report includes the observed detections for likely diurnal, and likely nocturnal species, and for ecological guilds of interest (e.g., raptors, water-associated birds, passerines), for each of the facility types and suspected causes of death. Species composition of detections and the results of the bias trials are also reported. This report presents information related to the spatial distribution of detections, but no formal statistical analysis of the spatial distribution of carcasses will be conducted until the end of the monitoring year, given the limited data presently available.

2.0 METHODS

The BBCS describes the methods by which monitoring and certain analyses, including compilation of the overall fatality estimate, will occur. Below is an abridged description (see BBCS for detailed methods).

2.1 Standardized Carcass Searches

This section describes areas surveyed, the timing and frequency of searches, and the methods by which standardized searches were conducted to identify dead/injured birds and bats at the Project. Dead or injured birds and bats are called detections in this report to provide consistency in naming. This section also describes the methods for conducting carcass removal and searcher efficiency trials; how data were reported and analyzed; and the methods for producing fatality estimates for the Project.

2.1.1 *Areas Surveyed*

Standardized carcass searches were conducted at sampling units, which include the solar arrays (Table 1, 2; Figure 2); the “fenceline” defined as the perimeter fence for the Project (Table 1, Figure 2); and the gen-tie line (from the Project fence to the Red Bluff Substation on the south side of I-10; Table 1, Figure 3). Some overhead lines co-occur with solar arrays (medium voltage overhead lines [MVOH]). The MVOH were part of standardized carcass searches to the extent that they co-occured with solar arrays included in the sample (Table 2; Figure 2).

Table 1. Areas included in standardized carcass searches at the Desert Sunlight Solar Farm Project during summer (June 01 – August 30) 2015.

Project Component	Total Size	Units	% of Component Searched
Solar arrays	1045.9	Hectares	29.5[1]
Fence	16.7	Kilometers	99.0[2]
Gen-tie line	19.2	Kilometers	47.9[3]

[1] Percent area that was searched in summer 2015. Slightly less than 30% total because of unequally-sized arrays.

[2] 74.4% of the fence is fully accessible and surveyed following the standard protocol, while approximately 25% of the fence is surveyed from a distance. Fatality rates estimated for sections of the fence that are sampled were extrapolated to sections of the fence where the standard monitoring protocol cannot be used, as described in section 4.2.6 of the approved Desert Sunlight BBCS. A very short segment near the gate is not sampled due to restoration activities.

[3] 52.1% of the gen-tie will be sampled in 2016.

Figure 2. Areas of standardized searches and detections (those made during searches and those made incidental to operations and maintenance) at the solar field, fence, and overhead lines within the fence at Desert Sunlight Solar Farm Project during summer (June 01 – August 30) 2015.

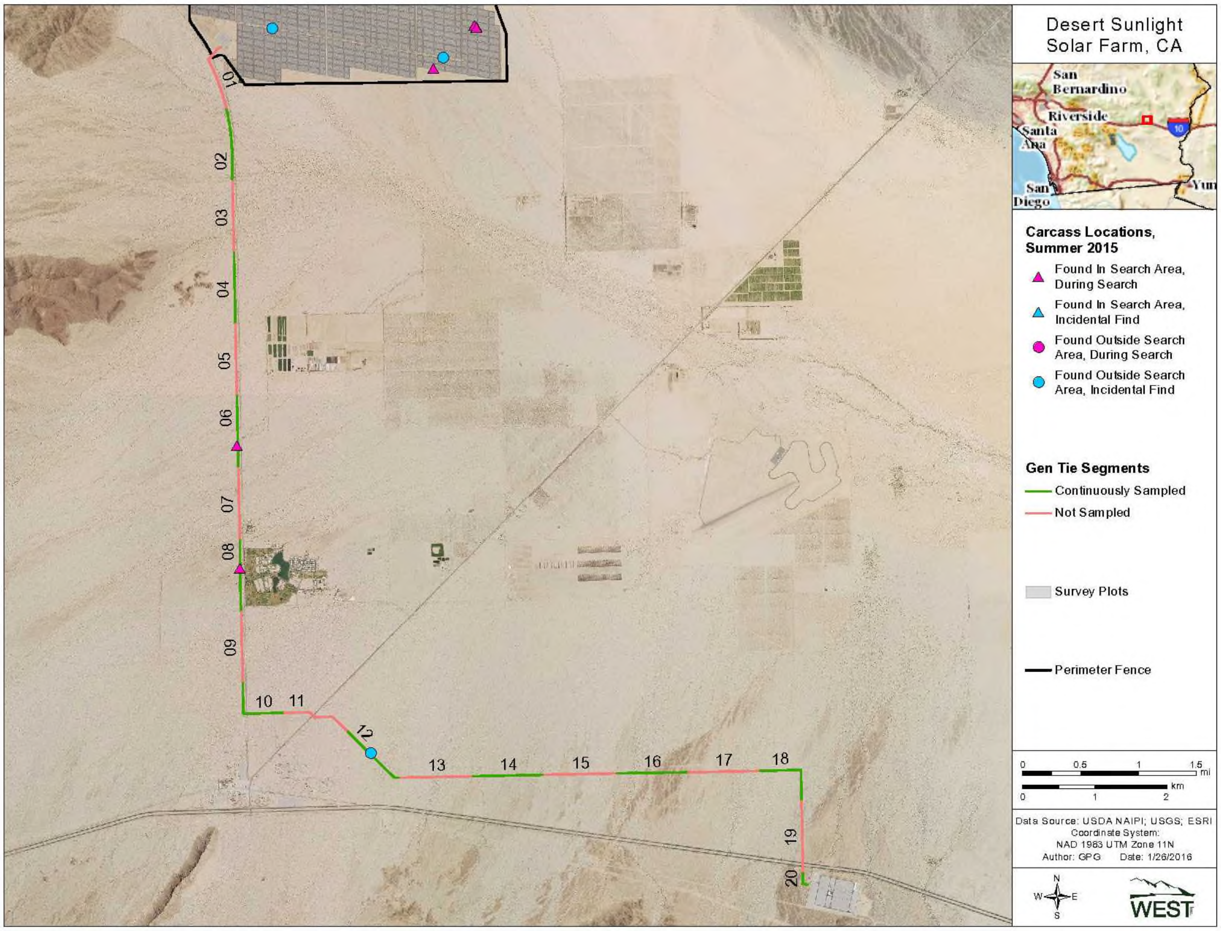

Figure 3. Areas of standardized searches and detections (those made during searches and those made incidental to operations and maintenance activities) along the generation tie line at the Desert Sunlight Solar Farm Project during summer (June 01 – August 30) 2015. Detailed maps of detections along the line are presented in Appendix A.

To ensure a balanced distribution of sample units in the solar field (defined as the collection of all photovoltaic [PV] solar panels), the entire field was divided into ten strata, and individual sampling units were randomly selected within each stratum to compose an approximately 30% sample. This sampling design ensures that units included in the sample were not spatially clumped within the solar field. The solar field consists of arrays of solar panels (referred to as a solar array) that are either 70-m or 140-m wide. The sample includes 133 of each type of array. There are 2,580 70-m rows, and 3,900 140-m rows in the sample.

2.1.1 *Search Frequency and Timing*

Standardized searches occurred during the summer survey season, which includes the period from June 01 through August 30, 2015. All project components included in standardized searches were surveyed four times during summer. All searches took place during daylight hours from 05:40 to 14:08.

As specified in the approved Desert Sunlight BBCS, the average search interval for all Project components included in standardized carcass searches during summer was 21.0 days (median 21.0 days). Slight variation in search interval was anticipated due to weather and logistical delays.

Table 2. Area and proportion of solar arrays that are and are not associated with overhead lines at the Desert Sunlight Solar Farm Project, Riverside County, CA.

	Line-associated[1]	Not line-associated	Proportion line-associated
Entire facility	89.4 ha	956.5 ha	0.09
Standardized searches	32.2 ha	291.0 ha	0.10

[1] Line-associated area was estimated as the area of any array that fell within the 30-m strip transect below the MVOH.

2.1.2 *Search Methods*

Standardized carcass searches were performed by BLM-approved biologists, in accordance with methods outlined in the BBCS.

Within the solar field, arrays of solar panels were surveyed by observers traveling on foot. A distance sampling approach was used, whereby biologists slowly walked a transect line along the ends of rows of solar panels in a direction perpendicular to the rows, searching ahead and to the side within the array for bird and bat detections. Biologists scanned out to a maximum perpendicular distance of approximately 70 m from the transect. Biologists carried binoculars to allow them to verify the presence of a detection versus rocks or vegetation. Once a detection was confirmed, the distance of the detection to the transect line was estimated using laser range finders. Each array included in the sample was searched by observers walking two transects – one on the west side and one on the east side of the array with observers looking toward the center of the array.

As soon as a carcass was detected, it was photographed, and data were recorded according to specifications outlined in section 7.2.5 of the approved Desert Sunlight BBCS. Carcasses were then immediately retrieved from their location on the ground, labeled, and placed in a freezer on site.

Most (74.4%) of the length of fenceline (approximately 10 miles) was searched from a vehicle using the standard protocol (Figure 2). Biologists searched a 6-m wide strip transect centered on the fence from the inner perimeter. Travel speed was below five miles per hour (mph) while searching. Some sections along the fence cannot be driven close to the fence line. The fence line along the western edge of the Project is drivable but the road is approximately 15 m away from the fence and the road and fence are separated by a drainage ditch. The fence along this section is covered with a tan tarp and trees and shrubs have been planted to reduce visibility of the project from the west. Additions of vegetation and the tarp likely reduce potential for bird collision with the fence. This section of the fence was driven to document carcasses, but detections along this portion of the fence are not included in adjusted fatality estimates because detection rates are likely very low. As specified in section 4.2.6 in the approved Desert Sunlight BBCS, we assume that fatality rates are similar between the portion of fence that was searched and the portion that was not. A separate section of the fence in the southeastern corner of the Project cannot be driven because the eastern edge of the berm that bounded construction ponds is too narrow for a vehicle. Along this portion of the fence, the observer stopped at both north and south ends of the berm and used binoculars to search for carcasses. Finally, the road along a portion of the southwest fence line near the entrance gate is approximately 30 to 50 m from the road and is separated from the fence by an area that has recently undergone vegetation restoration. This area was eliminated from sampling. Fatality rates estimated for sections of the fence that were sampled were adjusted to account for the proportion of fence not sampled with the standard monitoring protocol, as specified in section 4.2.6 of the approved Desert Sunlight BBCS.

The gen-tie line was searched using a 30-m wide strip transect (i.e., 15 m of ground on either side of the overhead line). Sample units along the gen-tie line were chosen by dividing the total length of line from the Project fence south to the Red Bluff Substation just south of I-10 into 1-km segments. Thus, a 47.9% sample of the total length of the line was searched (Figure 3). Biologists slowly walked every other 1-km segment of the line, meandering the width of the strip transect, scanning for dead or injured birds or bats within 15 m (49.2 ft) of the overhead line.

For each detection, a suspected cause of death or injury was assigned based on evidence available from the detection, evidence available on Project infrastructure, and proximity of the detection to Project infrastructure. Detections that had evidence of scavenging and lacked evidence on Project infrastructure were assigned as “unknown” because it cannot be determined whether the event was caused by predation or interaction with project infrastructure. Detections that were intact (i.e., no evidence of scavenging) and located in close proximity to Project infrastructure (e.g., found directly beneath overhead lines) had a suspected cause of death attributed to the respective Project component. However, it should be noted that there is substantial uncertainty associated with cause of death assignments because no events were directly observed. Detections assigned to the “unknown” category were included in fatality estimates if they were located within standardized carcass search areas, and all detections made during the summer season are reported here.

2.2 Carcass Persistence Trials

Carcass persistence trials were conducted throughout the summer period. Carcasses from three size classes (small [0-100 g], medium [101-999], and large [1000+ g]) were used for trials. The small size class comprised house sparrows (*Passer domesticus*) and 2-3 week old coturnix quail (*Coturnix coturnix*), the medium size class comprised rock pigeons (*Columba livia*), chukar (*Alectoris chukar*), and older coturnix quail, and the large size class comprised hen mallard (*Anas platyrhynchos*) and hen ring-necked pheasant (*Phasianus colchicus*).

2.2.1 *Carcass Persistence Data Collection*

To quantify carcass persistence rates, 15 small, 10 medium, and 5 large carcasses were randomly placed and monitored along the gen-tie line during summer 2015. Within the solar arrays and along the perimeter fence, the same numbers of each size category were placed, for a total of 60 carcass persistence trials at Desert Sunlight during the summer season, as specified in the approved Desert Sunlight BBCS. By placing carcasses inside (within arrays and along inner perimeter of the fence) and outside (along the gen-tie) the project fence, the possibility that there are different carcass persistence rates inside and outside the project fence is accounted for. Fifteen carcasses within the Project fence (within solar arrays and along the fence) were monitored using motion-triggered digital trail cameras, while the remaining carcasses were visited on foot, for 30 days or until the carcass had deteriorated to a condition at which it would no longer qualify as a documentable fatality. No carcasses along the gen-tie line were monitored with cameras because of theft and vandalism concerns. Carcasses without trail cameras were visited and photographed once per day for the first four days, and then every three to five days until the end of the monitoring period. To avoid training scavengers to recognize cameras as “feeding stations”, trail cameras were installed five days before specimens were placed, and two fake cameras without bias trial carcasses were also placed within the Project fence and periodically moved to new locations within the fence. Periodic ground-based checking of carcasses with trail cameras also occurred to guard against misleading indicators of carcass removal, such as wind blowing the carcass out of the camera’s field of view. To minimize potential bias caused by scavenger swamping (Smallwood 2007, Smallwood et al. 2010), carcass-persistence specimens were distributed across the entire Project, not just in areas subject to standard searches, and trials were initiated in smaller numbers on three different dates throughout the summer season.

2.2.2 *Estimating Carcass Persistence Times*

Carcass persistence trials were checked daily during the first four days and then every three to five days until the 30-day trial length was reached. Measurements of carcass persistence rates were subject to censoring. In this context, censoring refers to the instance when a value (e.g. days a carcass is present before being removed) may not be known exactly, but is known to be within a finite range. For example, suppose a carcass was checked on day 7 and was present, and was checked again on day 10, but was found to be missing. The exact time until removal is unknown; however, it is known that the carcass became unavailable at some point between 7 and 10 days. This carcass would be considered “interval censored”. Similarly, if a carcass lasts the entire 30-day trial period, that carcass is “right censored”— it is known that the carcass lasted at least 30 days, but it may have persisted longer. Because carcass persistence data were censored, persistence was analyzed using methods that can accommodate censored data and still produce unbiased estimates of the probability of persistence (Therneau 2015, Therneau and Grambsch 2000). It is beyond the scope of this document to provide statistical foundations of censored-data survival models but functions identical to those provided with the USGS-developed fatality estimator software (Huso et al 2012) were used to fit survival models to the censored carcass persistence data, and some background is available in the documentation provided with that software.

The USGS software used to estimate carcass persistence calculates the period over which there is less than a 1% chance for a carcass to persist. The 'effective search interval' is defined as the shorter of the period during which there is less than a 1% probability that a carcass persists, and the actual search interval (Huso 2010). The probability of persistence is given for the effective search interval, and the probability that a carcass persists through the actual search interval is equal to p (persist through effective search interval) * effective search interval / actual search interval.

There were four distributions implemented in survival models used to estimate the probability a carcass is unscavenged and available to be found at the end of the search interval (*r)*: exponential, Weibull, loglogistic, and lognormal. These four distributions exhibit varying degrees of flexibility in order to model a wide variety of distributions of persistence time. Akaike's Information Criterion adjusted for sample size (AICc; Akaike 1973) was used to rank the fit of each survival model with combinations of the covariates carcass size, Project component, season, and visibility, to observed carcass persistence data.

2.3 Searcher Efficiency Trials

Searcher efficiency trials were conducted throughout the summer period. Carcasses from three size classes (small, medium, and large) were used for trials. The small size class comprised house sparrows and 2-3 week old coturnix quail (*Coturnix coturnix*), the medium size class comprised rock pigeons, chukar, and older coturnix quail, and the large size class comprised hen mallards and hen ring-necked pheasants.

2.3.1 *Searcher Efficiency Data Collection*

Training of biologists on the Project-specific protocol and early assessments of habitat conditions within the solar arrays suggested that the amount of cobble present in the soil may be an important factor influencing searcher efficiency. To satisfy requirements regarding consideration of visibility class per the BBCS and address the influence of cobble cover on searcher efficiency, sample units in the solar arrays and along the gen-tie were stratified by cobble cover and assigned to one of two classes (<15% and >15% cobble cover). Classes were determined by making ocular estimates of cobble cover at each sample unit and then evaluating the frequency histogram of sample units across the range of estimated cobble cover (Figure 4). A natural break point was identified at 15% cobble cover, so the same value was chosen as the break point that defined the two cobble cover classes. For most seasons, In the solar arrays, two sets of searcher efficiency trials will be conducted (one set in each cobble cover class; *n* for each class= 15 small birds, 10 medium birds, and 5 large birds as agreed upon in section 7.4 of the approved Desert Sunlight BBCS). During summer 2015, all searcher efficiency trial carcasses were inadvertently placed in the low cobble cover class, precluding any tests of the effect of cobble cover class on searcher efficiency in the solar arrays. Additional trials will be conducted in the winter period in cobble to address this oversight and small sample size. Along the gen-tie, visibility was expected to be related to vegetation and rock cover. Thus, searcher efficiency trials along the gen-tie occurred in two visibility classes (*n* for each class = 15 small birds, 10 medium birds, and 5 large birds (easy: ≥90% bare ground, vegetation <6" tall; and more difficult: <90% bare ground, vegetation ≥6" tall). Inadvertently, one large carcass was not placed and one extra small carcass was placed during summer, so total sample size for large carcasses along the gen-tie was nine, and for small carcasses was 31. Thirty searcher efficiency trial carcasses (*n* = 15 small birds, 10 medium birds, and 5 large birds) were placed along the fence in the only visibility class present on the fence (easy visibility). Thus, during summer, a total of 150 searcher efficiency trials occurred at the Project. Locations for trials were chosen by taking a randomized sample of all locations included in standardized carcass searches.

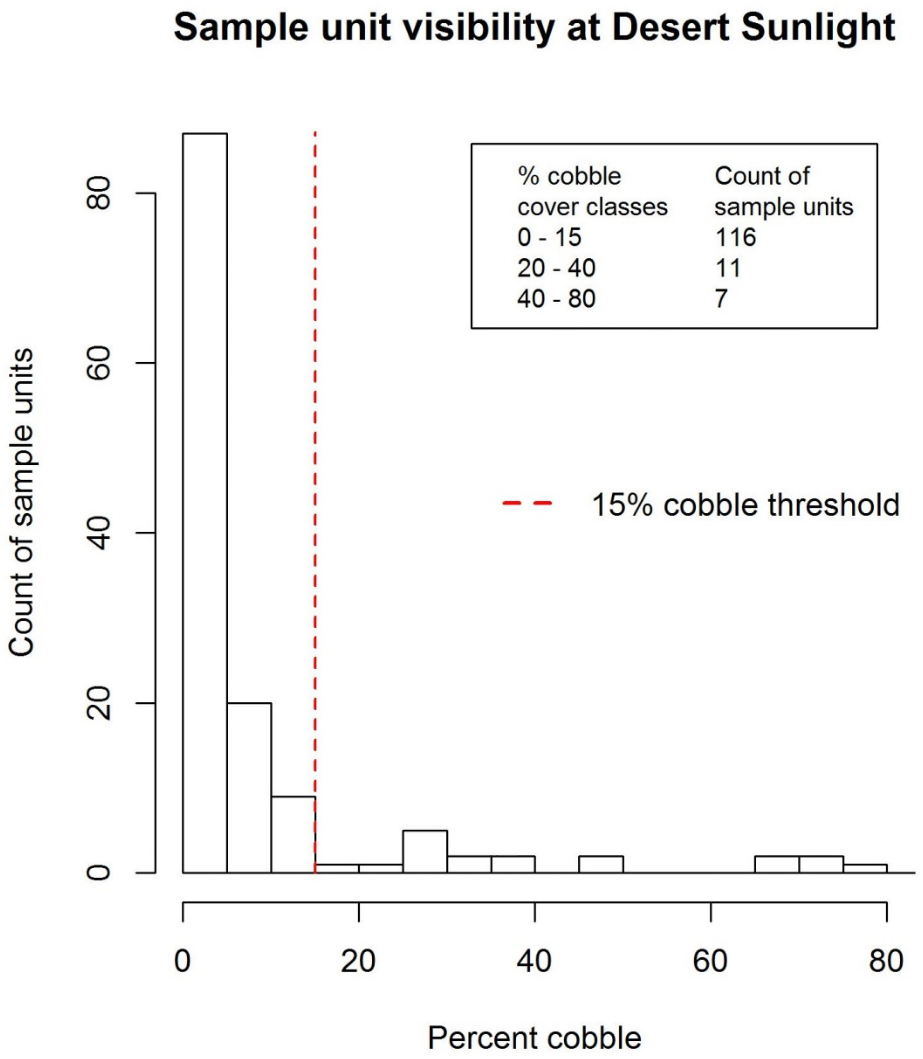

Figure 4. Frequency histogram of sample units (in the arrays only) at Desert Sunlight Solar Farm Project by estimates of cobble cover. Based on this distribution, each sample unit was assigned to one of two classes of cobble cover (<15%; >15%).

2.3.2 *Estimating Searcher Efficiency*

Searcher efficiency at Desert Sunlight was estimated separately for linear features (the project fence and the generation tie line), and the solar arrays, reflecting the different search methods used on arrays and linear features. For linear features, logistic regression models were fit to searcher efficiency data and AICc was used to compare models. Models including effects of carcass size (three classes), visibility (two classes; gen-tie only), and season were compared to each other and the null model. Model selection indicated that the most supported model included main effects of Project component, carcass size, and season. Once the most supported model was chosen and appropriate classes identified, searcher efficiency, or the proportion of carcasses detected, *p*, was calculated for each class using the following equation:

$$p = \frac{Number\ of\ Carcasses\ Observed}{Number\ of\ Carcasses\ Available}$$

The data for this analysis included all searcher efficiency trial carcasses from the summer 2015 season.

For the solar arrays, searcher efficiency was evaluated using a distance sampling approach (Buckland et al. 1993). Distance sampling assumes perfect detection on the transect line (at distance = 0), an assumption that is likely valid in the solar arrays given the relatively flat & vegetation-free nature of the soil surface. A curve is fitted to the observed carcass data that predicts probability of detection as a function of distance from the transect line. The mean value of this function over a specified distance, *w,* is equal to the average searcher efficiency for a transect of width *w*. The mean value of the detection curve is the integral of the detection function calculated between 0-m and the maximum survey distance (*w;* half the width of the solar array row), divided by the maximum survey distance:

$$p = \frac{\int_0^w f(x)dx}{w},$$

where f(x) is the detection function evaluated at distance, *x*.

One departure in the methods used here, relative to the methods presented in Buckland et al. (1993), was that for this study the detection function was estimated using trial carcasses, which meant that there were both presence (detected) and absence (not detected) data available to fit the detection function (Figure 5). The availability of both presence and absence data means that the detection function can be estimated using only trial carcasses whose distribution is known. Therefore the detection function, the average searcher efficiency among the arrays and the final fatality estimate within the arrays are all insensitive to the spatial distribution of carcasses within individual arrays, and the overall searcher efficiency estimate is valid even if the distribution of carcasses among the arrays is not uniform.

Distances of trial carcasses (trials both found and missed) from the transect line were used to fit a half-normal detection function for searches among the arrays (Figure 5). The half-normal detection function is a commonly used function for distance sampling surveys (Buckland et al. 1993). The detection function was fit with and without covariates (carcass size, season, or no covariates) and AICc indicated that the most supported among these models included only carcass size as a covariate.

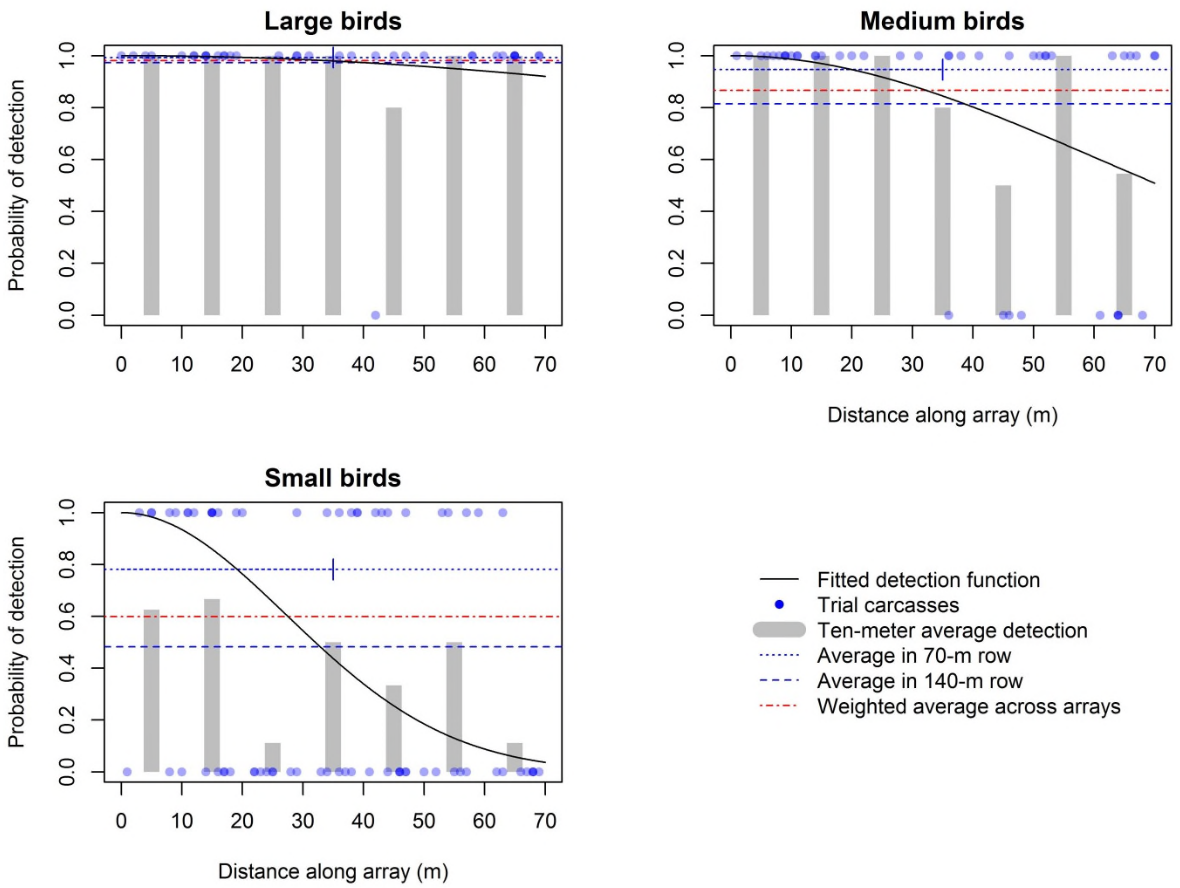

Figure 5. Estimated detection probabilities for bird carcasses by size class across all available seasons used for summer (June 01 – August 30) 2015 fatality estimates at the Desert Sunlight Solar Farm Project, Riverside County, California. Distance sampling was used when searching solar arrays only. Average probability of detection over 70-m (arrays relying on a 35-m viewshed) and 140-m (arrays relying on a 70-m viewshed) panel rows in solar arrays are presented.

Because the solar arrays were surveyed by searchers who walked down both sides of the rows of panels, the width of the search transect was specified as half the width of the rows of panels. For larger birds, there is almost certainly a non-zero detection probability beyond this distance but the bias that occurs by ignoring this non-zero detection probability is conservative (i.e. the searcher efficiency is underestimated). Some solar arrays have row widths of 70 m (search transect width of 35 m) and some have row widths of 140 m (search transect width of 70 m). The weighted average searcher efficiency is calculated based on the number of panel rows of each length in the survey sample:

$$p_{weighted\ average} = \frac{n_{70}}{n} \times \frac{\int_0^{35} f(x)dx}{35} + \frac{n_{140}}{n} \times \frac{\int_0^{70} f(x)dx}{70},$$

where $n_{70} = 2580$ is the number of 70-m rows in the sample, $n_{140} = 4020$ is the number of 140-m rows in the sample, and *n* is the total number of rows in the sample. Searcher efficiency was higher for the arrays with a width of 70 m, and overall searcher efficiency was estimated as a weighted average based on the proportions of 70-m arrays and 140-m arrays in the sample units.

2.4 Fatality Estimator

Fatality rate estimation is a complex task due to several variables inherent to every fatality monitoring study. Carcasses may persist for variable amounts of time due to local scavenger activity or environmental conditions leading to carcass degradation over time. Carcasses and feather spots are also detected with varying levels of success based on carcass characteristics and ground cover (e.g., vegetated areas underneath the gen-tie line versus cleared areas beneath solar panels). For these reasons, it is generally inappropriate to draw conclusions based on the raw number of fatalities alone. The desire to estimate fatalities given these variables has driven the development of several statistical methods for estimating fatalities (e.g., Smallwood 2007, Huso 2010, Korner-Nievergelt 2011). All of these fatality estimation methods share a similar underlying model. Generally, the fatality estimation for a given site may be written as:

$$F=C/rp,$$

where *F* is the total number of fatalities, *C* is the number fatalities detected and included in fatality estimation*, r* is the probability a carcass is not scavenged and available to be found at the end of the search interval, and *p* is the probability of detecting a carcass (Huso 2010). Huso (2010) describes the use of a binomial model to estimate the probability of carcass detection; in the present study, the binomial carcass detection model was used to calculate fatalities at project linear features (fence, overhead lines), and the weighted average probability of detection based on distance sampling (described above) was used to estimate probability of detection within the solar arrays.

All fatality estimates were calculated using the Huso estimator (modified to accommodate the distance-sampling based estimate of searcher efficiency in the solar arrays), as well as 90% confidence using bootstrapping (Manly 1997). Bootstrapping is a computer simulation technique that is useful for calculating point estimates, variances, and confidence intervals for complicated test statistics. A total of 1,000 bootstrap replicates was used for each of the variables, including searcher efficiency (*p*), probability of a carcass persisting to the next search ($\hat{r}$), adjusted search interval and observed fatalities. From these bootstrap samples, the probability of available and detected was calculated and applied to the bootstrapped observed fatalities. The lower 5th and upper 95th percentiles of the 1,000 bootstrap estimates provide estimates of the lower limit and upper limit of an approximate 90% confidence interval on all estimates.

2.5 Incidental Reporting

Some detections were outside standardized search areas, or were within search areas but not observed during standardized searches. Such detections were found by WEST avian biologists and operational personnel and were considered "incidental" detections. When found by operational personnel, these detections were reported to WEST avian biologists for documentation. Data on incidental detections are reported here, as well as in the Desert Sunlight SPUT Avian Injury and Mortality Report Forms June – August 2015. All detections made in search areas during the reporting period were included in fatality estimates, regardless of whether they were detected incidentally or during searches.

3.0 MONITORING RESULTS

3.1 Summary of Avian Detections

During summer 2015, a total of 15 avian detections (including incidentals) of 11 identified species were recorded (Table 3). The most common identified species was common raven (*Corvus corax*) with three detections. Most detections (n = 11, or 73.3% of total detections) occurred in the solar arrays (Figures 2 and 3; Tables 4, 5, and 6). Ten (66.7%) detections were made during standardized carcass searches and five (33.3%) were documented as incidentals. No bats were detected during the summer season. For fresh carcasses, body weights and weather conditions the preceding nights are described in Appendix B.

Table 3. Number of individual bird detections, by species, during summer (June 01 – August 30) 2015 at the Desert Sunlight Solar Farm Project, Riverside County, California. LA = line-associated; NLA = non-line associated.

Common Name	Scientific Name	Migration Behavior*	Guild	LA Solar Array	NLA Solar Array	Fence	Gen-tie Line	Total
common raven	*Corvus corax*	resident	Corvids	-	2	1	-	3
white-winged dove	*Zenaida asiatica*	variable	Doves/Pigeons	-	-	-	1	1
black-throated sparrow	*Amphispiza bilineata*	diurnal	Grassland/ Sparrows	-	-	-	1	1
sora	*Porzana carolina*	nocturnal	Rails/Coots	-	-	-	1	1
Virginia rail	*Rallus limicola*	nocturnal	Rails/Coots	1	-	-	-	1
house wren	*Troglodytes aedon*	nocturnal	Wrens	1	-	-	-	1
mourning dove	*Zenaida macroura*	variable	Doves/Pigeons	-	1	-	-	1
Say's phoebe	*Sayornis saya*	diurnal	Flycatchers	-	1	-	-	1
northern rough-winged swallow	*Stelgidopteryx serripennis*	diurnal	Swallows	-	1	-	-	1
unidentified bird (small)	-	-	Unidentified Birds	-	1	-	-	1
unidentified bird (unknown size)	-	-	Unidentified Birds	-	1	-	-	1
unidentified grebe	*Aechmophorus sp.*	-	Waterbirds/ Waterfowl	-	1	-	-	1
western grebe	*Aechmophorus occidentalis*	nocturnal	Waterbirds/ Waterfowl	-	1	-	-	1
Total				**2**	**9**	**1**	**3**	**15**

* See literature cited for migration behavior references; information for most species was taken from the respective species accounts found in Birds of North America (BNA) Online (http://bna.birds.cornell.edu/bna/); where information on migration behavior was lacking in BNA accounts, Newton (2008) or Murray (2004) were used.

Table 4. Total avian detections by Project component and detection category during summer (June 01 – August 30) 2015 at the Desert Sunlight Solar Farm Project, Riverside County, California. Only carcasses found within search areas were included in fatality estimates.

	Inside carcass search area		Outside carcass search area	
Project Component	**Carcass search**	**Incidental**	**Carcass search**	**Incidental**
Fence	0	0	1	0
O&M Building	0	0	0	0
Gen-tie line	2	0	0	1
Solar arrays				
Line-associated	0	0	0	2
Non-line associated	7	1	0	1

Table 5. Total avian detections (including incidentals) by Project component and suspected cause of death during summer (June 01 – August 30) 2015 at the Desert Sunlight Solar Farm Project, Riverside County, California.

	Suspected Cause of Death*				
Project Component	**Collision**	**Predation**	**Other**	**Unknown**	**Percent of Total**
Fence	0	0	1	0	6.7
O&M building	0	0	0	0	0
Gen-tie line	2	0	1	0	20
Solar arrays					
Line-associated	1	0	1	0	13.3
Non-line associated	1	0	5	3	60
Percent of Total	**26.7**	**0**	**53.3**	**20.0**	**100.0**

* Suspected cause of death was assigned based on evidence available on the detection, evidence available on Project infrastructure, and proximity of detection to Project infrastructure. Detections that had evidence of scavenging and lacked evidence on Project infrastructure were assigned as “unknown” because it can’t be determined whether the event was caused by predation or interaction with project infrastructure. Detections that were intact (i.e., no evidence of scavenging) and located in close proximity to Project infrastructure (e.g., found directly beneath overhead lines) had a suspected cause of death attributed to the respective Project component. However, in the absence of a completed necropsy, there is some uncertainy associated with cause of death assignments because no events were directly observed.

3.2 Temporal Patterns of Avian Detections

The number of detections recorded daily during the reporting period ranged from zero to three (Figure 6). One detection was found per day with the exception of June 24 when three detections occurred. The number of detections per day represents those discovered during standardized carcass searches and incidentally.

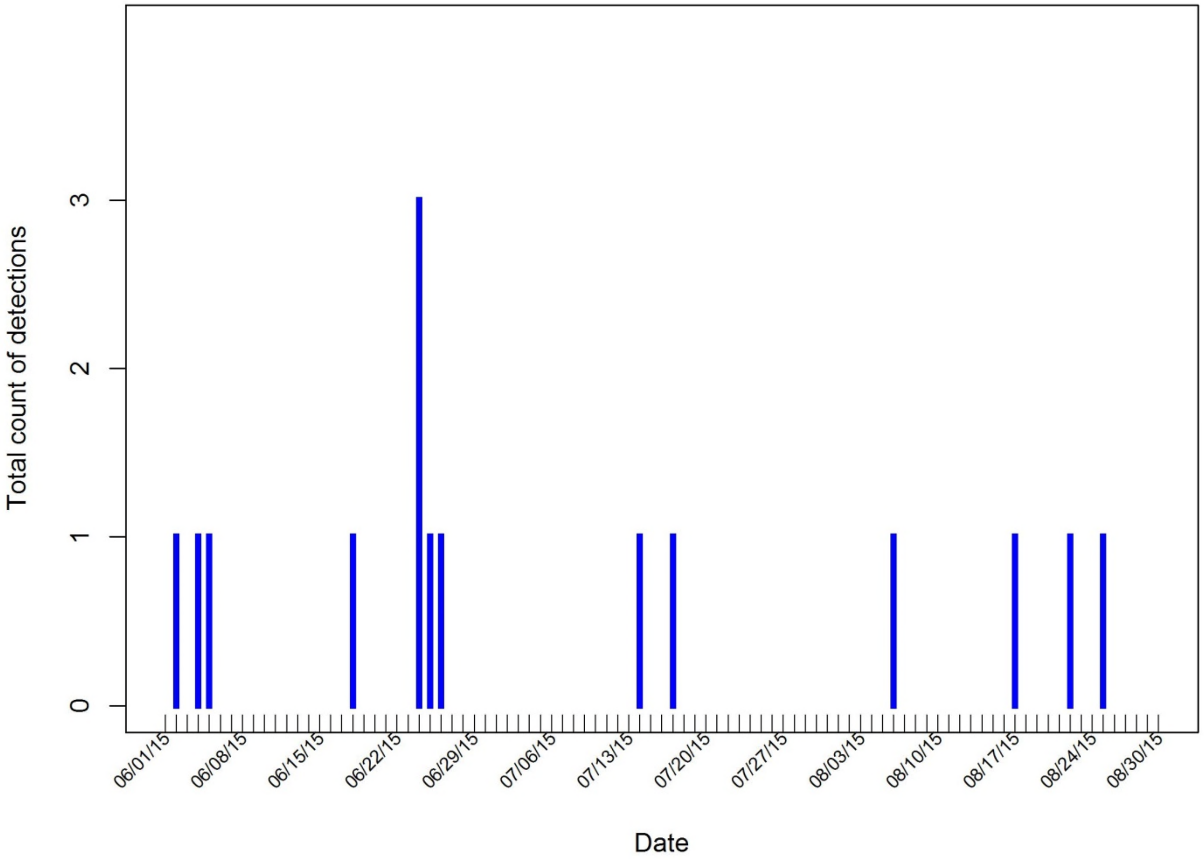

Figure 6. Total number of detections by date during summer (June 01 – August 30) 2015 at the Desert Sunlight Solar Farm Project, Riverside County, California.

3.3 Spatial Distribution of Avian Detections

3.3.1 *Detections by Project Component*

During the reporting period, detections were documented from the solar arrays, the northern section of the perimeter fence, and the gen-tie line; no detections occurred at the O&M building (Tables 3, 4, and 5). Of the 11 detections within the solar arrays, 18.2% (2) were associated either with overhead lines or arrays that co-occurred with overhead lines.

3.3.2 *Feather Spot Detections*

Five (33.3%) of the 15 detections consisted only of feather spots. Along the gen-tie, one of three detections (33.3%) was a feather spot. No detections along the fence were a feather spot. Four of 11 detections (36.4%) in the solar arrays were feather spots.

3.4 Detections of Injured Birds

No injured birds were detected during the summer 2015 season.

3.5 Summary of Bat Detections

No bats were detected during the summer 2015 season.

3.6 Carcass Persistence Trials

Data from carcass persistence trials were available from late winter, spring, and summer at the solar field and gen-tie line (n = 154 total). Based on carcass persistence data from late winter, spring, and summer 2015, survival models were compared for relative quality using the corrected AICc score, as suggested in Huso (2010). The AICc score provides a relative measure of model fit and parsimony among a selection of candidate models, and provides a framework for testing hypotheses regarding which factors contribute to carcass persistence rates. Carcass size was tested as a potentially important variable, as larger carcasses tend to persist longer than smaller carcasses. Project component (solar arrays/fence, generation-tie line) was also included as a potentially important variable, as was season.

The model with lowest AICc score is typically chosen as the model with the most empirical support relative to other models tested; however, any model within two AICc points of the model with the lowest score is considered competitive (Burnham and Anderson 2004). The most supported model included main effects of season, carcass size, Project component, and interactions of Project component × season and Project component × size with a Weibull-distributed removal time. Given the main effect of season, further modeling efforts were restricted to data collected in summer only. The most supported model using only the summer data suggested an interaction between carcass size and Project component. Estimates of carcass removal time and persistence probabilities are reported in Table 6 from the most supported model, and estimates of proportion of carcasses remaining as a function of days since carcass placement are provided in Figure 7. The difference in carcass removal times between Project components is because scavengers likely occur in higher densities outside the perimeter fence.

Table 6. Mean carcass removal time and probability of a carcass persisting through the effective search interval (5.8 days) during the summer season (June 01 – August 30) at the Desert Sunlight Solar Farm Project, Riverside County, California.

Carcass size	Project component	Mean removal time (days)	Median removal time (days)	Probability of persistence
Small	Arrays/fence	15.5	11.5	0.63
Small	Gen-tie lines	1.37	0.5	0.22
Medium	Arrays/fence	19.2	22.5	0.73
Medium	Gen-tie lines	14.8	15.5	0.60
Large	Arrays/fence	-*	-*	1.00
Large	Gen-tie lines	0.9	0.5	0.22

* Mean and median removal time was not estimated because no removal was observed for large carcasses within the solar field.

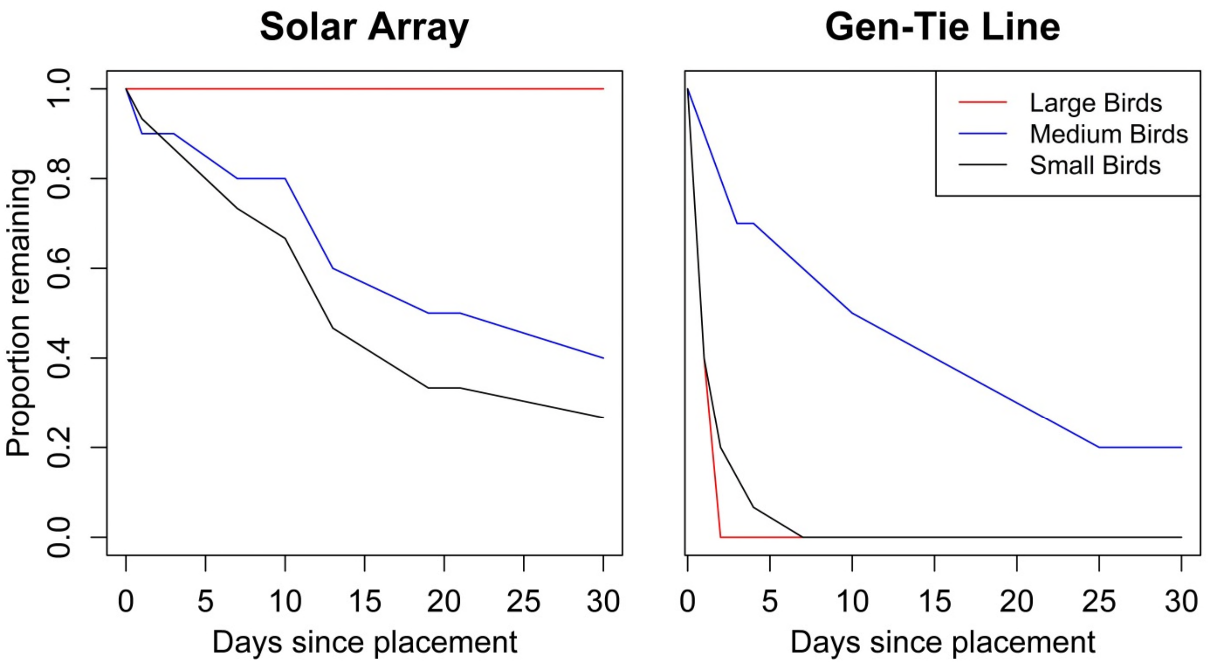

Figure 7. Proportion of trial carcasses remaining as a function of days since placement and carcass size class (n = 30, 20, and 10 for small, medium, and large size classes, respectively) during the summer (June 01 – August 30) 2015 season at the Desert Sunlight Solar Farm Project, Riverside County, California.

3.7 Searcher Efficiency Trials

During the reporting period, a total of 150 searcher efficiency trials were placed at the Project. Most trials were available to be found, but some disappeared before or during the trial. Overall, 60 trials were placed in the solar arrays and 44 were available to be found; 30 trials were placed along the perimeter fence (inner perimeter only) and 30 were available to be found; and 60 trials were placed along the gen-tie line and 55 were available to be found. Searcher efficiency trials were conducted on each observer in approximate proportion to the number of searches they conducted at the Project, as follows: Sarah Nichols (number of trials available to be found: 84); Jennifer Johnson (67), and Pam Bullard (5).

In the solar arrays, the model that included an effect of carcass size was chosen as the most supported model to estimate searcher efficiency. Thus, the data used to produce the following estimates of searcher efficiency include trials available to be found during February, spring, and summer (n = 180). Within the solar arrays, searcher efficiency was: 60.0% for small birds, 86.6% for medium birds, and 98.1% for large birds (Figure 5).

For linear Project components, the model that included an effect of carcass size, Project component, and season was chosen as the most supported model to estimate searcher efficiency. Thus, the data used to produce the following estimates of searcher efficiency include trials available to be found during summer only along the fence (n = 30) and the overhead lines (n = 55). Along the fence, searcher efficiency ranged from 87.5% to 100% depending on carcass size class. Along overhead lines, searcher efficiency ranged from 43.5% to 100%. Detailed estimates of searcher efficiency estimates specific to each component and carcass size are reported in Appendix C.

3.8 Fatality Estimates

Fatality estimates were calculated separately for each component (solar arrays, fence, and overhead lines). Ultimately, five detections were excluded from the fatality analysis because they were found outside standardized search areas. All 15 detections made during summer are reported in Table 3. Detections used in the analysis, bias corrections, summer fatality estimates, and 90% confidence intervals for summer fatality estimates are detailed in Appendix C.

Table 7. Status of detections during the summer (June 01 – August 30) 2015 season at the Desert Sunlight Solar Farm Project, Riverside County, California. All detections outside the search area were excluded from the fatality analysis, regardless of whether they occurred during a standardized carcass search or incidentally.

	Carcass search	Incidental detection	*Pushed to next season's fatality estimate	*Pulled from previous season's fatality estimate
Inside search area	9	1	0	0
Outside search area	1	4	0	0

* Incidental detections occurring after the last standardized carcass search in a season are considered for inclusion in the fatality analysis for the following season. This is consistent with the assumption we make throughout the monitoring seasons; that carcasses found incidentally would have been available to be found on the next scheduled search. This assumption may result in some carcasses found during one season but considered in the following season's fatality analysis. Once a carcass has been moved to a different season's analysis it is still subject to the same criteria for inclusion or exclusion based on location (in versus out of a searched area) and carcass age (greater than versus less than the search interval).

During summer 2015, there were an estimated total 148 carcasses (90% CI: 10 – 365) at the Project. Of these, 44 carcasses (27.5%; 90% CI: 8 – 64) were estimated for the solar arrays and 104 carcasses (66.9%; 90% CI: 2 – 339) were estimated for the gen-tie line. While we are required to report the gen-tie estimates per the approved BBCS, these estimates are not reliable due to the high rates of scavenging that were observed during the limited trials at the gen-tie and the low number of carcasses detected (n = 2 in the fatality analysis). No carcasses were estimated for the perimeter fenceline because there were no detections made along the fence. All of these estimates should be interpreted with caution because variance estimates are in general unreliable when carcass counts are low (< 5 per category). The TAG has asked for both the estimates and confidence intervals for this project with the appropriate caveat added. There were an estimated 17 fatalities per 1000 acres (within the solar field only; 44 estimated carcasses/2,585 acres) and an estimated 0.08 fatalities per nameplate MW (44 estimated carcasses/550 MW) within the solar field. A complete list of estimates for each Project component and carcass size class with confidence intervals is presented in Appendix C.

4.0 DISCUSSION

The 2015 summer season represented the second full season of standardized monitoring at Desert Sunlight per the BBCS. Searcher efficiency trials and carcass removal trials were conducted concurrently at the solar arrays, fencelines, and along the gen-tie line. Data from these trials were used to produce fatality estimates adjusted for searcher efficiency and carcass persistence bias. Although these estimates were produced from a statistically robust sample, only limited inference may be drawn from two seasons of data. These results should be considered preliminary because estimating carcass persistence, searcher efficiency, and adjusted numbers of fatalities within each season represents information based on a limited sample size. As more data are collected throughout the monitoring year (and additional quality assurance/quality control measures occur, for example characterizing feather spots to species or size class), data from all seasons may be pooled. At that time, data will be tested for seasonal differences retrospectively, but because seasonal estimates will be produced from the much larger annual data set, they may differ from what is reported here because they are based on a larger, more informative sample.

4.1 Carcass Persistence and Searcher Efficiency Trials

The degree to which carcasses persist on the landscape depends on a variety of factors reflecting seasonal and inter-annual variation in habitat, climate, and the scavenger community. The composition and activity patterns of the scavenger community often vary seasonally as birds migrate, new juvenile birds and mammals join the local population, and mammalian scavengers variably hibernate or estivate. The scavenger community may also vary substantially from year to year because of variation in annual reproduction and survival related to changes in landscape condition. Climatic conditions that vary seasonally and annually also may contribute to variation in carcass decay and removal rates due to variation in temperatures, solar insolation, wind patterns, and the frequency of flooding events. Thus, rates of carcass persistence reported here should be interpreted cautiously as they may change over the coming months.

Fatality estimates are influenced by the relationship between carcass removal dynamics and search intervals. In practical terms, longer search intervals reduce average probability that a carcass persists until the next search. In terms of the analysis, this can manifest as a lower probability of persistence through the effective search interval, or an effective search interval that is shorter than the nominal search interval. In either case, the adjustment to carcass counts due to carcass removal dynamics is calculated as

$$\frac{length\ of\ effective\ search\ interval}{\begin{array}{c}length\ of\ nominal\ search\ interval * average\ probability\ of\ persistence\\ through\ the\ effective\ search\ interval\end{array}}$$

The adjustment to estimated fatality for carcass removal increases with longer search intervals, and the variance in the estimate may increase, also.

Searcher efficiency was influenced by Project component, carcass size, and season. In the solar arrays, searcher efficiency was high (> 0.5) for all carcass size classes and this is likely influenced by the limited vegetation cover beneath solar panels. Beneath the gen-tie line, vegetation cover is higher in some portions of the strip transects, but results reported here support the hypothesis that visibility class is not a factor in searcher efficiency along the lines during summer. Placement of trial carcasses in both difficult and easy visibility classes ensures that the adjustment due to searcher efficiency accounts for both visibility classes, even if there is a real difference in searcher efficiency that cannot be detected with the trial data.

For the current analysis, searcher efficiency in the solar arrays was assumed to be predicted by a half-normal distribution. For future analyses, AICc will be used to compare and choose the most supported among multiple detection functions.

4.2 Distribution of Fatalities and Fatality Estimates

The number of detections was more or less evenly distributed across the summer season, and there were no clear associations between number of detections and date. Given the small number of detections overall, it is premature to draw any conclusions about the spatial distribution of carcasses.

Composition of detections during summer 2015 included eight avian guilds. Corvids comprised the majority of detections (n = 3): there were two detections each within the doves/pigeons, rails/coots, and waterbirds/waterfowl guilds. No bats have been detected since monitoring began at the Project.

Detections attributed to an unknown cause accounted for 20.0% of all detections (68% of which were feather spots) during the reporting period, and all those attributed to an unknown cause were found in the solar arrays. Of the 11 detections made in the solar arrays, 36.4% were feather spots. Determining a cause of mortality from a feather spot is challenging because there is rarely visible evidence available on which to determine a cause of death. Thus, feather spots with an unknown cause of mortality could be encountered anywhere birds occur, and an unknown cause of a sizeable proportion of the carcasses is not unique to the Project. Further, game cameras trained on carcasses for carcass persistence trials at the Project have documented multiple feather spots originating from a single trial carcass. Ravens and turkey vultures, and possibly roadrunners, dislodge feathers from their attachment to the skin of carcasses during the scavenging process. There are a very large number of potential feather spots present on a single bird carcass (because a feather spot is defined as at least two or more primary flight feathers, at least five or more tail feathers, or two primaries within five m (16.4 ft) or less of each other, or a total of 10 or more feathers of any type concentrated together in an area of three square m). The relatively large proportion of feather spots (33.3%) among the detections for the Project as a whole may inflate the fatality estimate when unknown cause detections are included based on the potential for multiple feather spots resulting from one fatality, feather spots resulting from predation not associated with the facility, or other causes. However, feather spots are included in the analysis here to provide a more conservative estimate of fatality.

EXECUTIVE SUMMARY

Avian and bat monitoring surveys were conducted from June 01 to August 30, 2015 (the reporting period) at Desert Sunlight Solar Farm Project (Project) in accordance with the Project's Bird and Bat Conservation Strategy (BBCS). For logistical reasons, fall monitoring began on Monday, August 31, 2015. Specifically, standardized carcass searches, searcher efficiency trials, and carcass persistence trials were conducted. This report represents the second seasonal report for the first year of monitoring, and summarizes monitoring methods and results for those surveys based on the procedures and requirements specified in the BBCS. This report and the other interim quarterly reports are considered preliminary summaries of data and information for the seasonal monitoring periods. Final information from all four quarterly monitoring periods will be included in a comprehensive final annual report.

Included in this report are data from standardized carcass searches conducted during the summer season at the Project, defined as June 01 to August 30, 2015. Standardized carcass searches were conducted 1) in the solar field, consisting of a random stratified 29.5% sample of solar photovoltaic (PV) panels, 2) along inner portions of the fenceline, resulting in 74.4% of the length of the perimeter fence, and 3) along 47.9% of the total length of generation-tie (gen-tie) line from the Project fence to the Red Bluff Substation located south of Interstate 10 (I-10). Searches conducted within the summer season had intervals of approximately 21 days.

All bird and bat fatalities and injuries that were discovered by observers, referred to as "detections" in this report, including those found incidentally and during standardized carcass searches, were documented. During the reporting period, 15 avian detections were made, and there were no detections of bats.

According to specifications of the BBCS, avian detections were categorized by likely diurnal or nocturnal migration behavior, ecological guild (e.g., raptors, songbirds, etc.), facility component, and suspected cause of death. These standardized carcass search results, along with searcher efficiency and carcass persistence rates from bias trials conducted on site, were applied to a fatality estimator model (Huso 2010) to provide a preliminary estimate of the number of fatalities that occurred at the Project during the reporting period adjusted for sources of bias. The estimate is considered preliminary because the annual report may pool information from bias trials and other data across seasons which could affect seasonal estimates.

During the reporting period, carcass persistence was influenced by carcass size and Project component. Small carcasses (0-100 g) in the arrays and along the fence (combined) had a 63% chance (90% confidence interval [CI]: 48 – 76%) of persisting through the effective search interval, medium carcasses (101 – 999 g) had a 73% (55 – 86%) chance, and large carcasses (1000+ g) had a 100% chance because no removal was observed. Mean removal time within the arrays for small and medium carcasses was 15.5, and 19.2 days, respectively; median removal time for small and medium carcasses was 11.5, and 22.5 days, respectively; mean and median removal times ~~was~~ were not estimated for large carcasses because no removal was

Comentado [FWS1]: Please explain why carcass persistence is influenced by project component.

Comentado [FWS2]: Please report median removal times and a figure showing the curve of # remaining over time.

observed. Along the generation tie-line, chances of persistence for small, medium, and large carcasses were 22% (14 – 26%), 60% (37 – 74%), and 22% (14 – 26%), respectively; mean removal time for small, medium, and large carcasses was, 1.4, 14.8, and 0.9 days, respectively; median removal time for small, medium, and large carcasses was, 0.5, 15.8, and 0.5 days respectively. The difference in carcass removal times between Project components is likely because scavengers occur in higher densities outside the perimeter fence.

Within the solar arrays, searcher efficiency averaged over all searchers and seasons (n = 180) was influenced by carcass size: 60.0% for small birds, 86.6% for medium birds, and 98.1% for large birds. Along the fence in summer (n = 30), searcher efficiency ranged from 87.5% to 100% depending on carcass size class. Along the generation tie-line in summer (n = 55), searcher efficiency ranged from 43.5% to 100%.

Comentado [FWS3]: Is this the searcher efficiency averaged for all observers? What is n?

Composition of detections during summer 2015 included eight avian guilds. Corvids comprised the majority of detections (n = 3): there were two detections each within the doves/pigeons, rails/coots, and waterbirds/waterfowl guilds. No bats have been detected since monitoring began at the Project.

Using the Huso (2010) fatality estimator model, modified to accommodate a distance-sampling approach to the estimation of searcher efficiency, during summer 2015, there were an estimated total 148 carcasses (90% CI: 10 – 365) at the Project. Of these, 44 carcasses (27.5%; 90% CI: 8 – 64) were estimated for the solar arrays and 104 carcasses (66.9%; 90% CI: 2 – 339) were estimated for the gen-tie line. While we are required to report the gen-tie estimates per the approved BBCS, these estimates are not reliable due to the high rates of scavenging that were observed during the limited trials at the gen-tie and the low number of carcasses detected (n = 2 in the fatality analysis). No carcasses were estimated for the perimeter fenceline because there were no detections made along the fence. All of these estimates should be interpreted with caution because variance estimates are in general unreliable when carcass counts are low (< 5 per category). ~~Other projects (e.g. Ivanpah) are not reporting estimates when carcass counts are less than or equal to five. However, t~~The TAG has asked for both the estimates and confidence intervals for this project with the appropriate caveat added. There were an estimated 0.017 fatalities per acre (within the solar field only; 44 estimated carcasses/2,585 acres) and an estimated 0.08 fatalities per nameplate MW (44 estimated carcasses/550 MW) within the solar field.

Comentado [FWS4]: IMPORTANT: WEST has said that it modified the Huso estimator, and despite several requests, those modifications have not been shared with the agencies. Until we understand what changes to the code were made, we are reserving judgment on these results.

Comentado [FWS5]: This supports increased frequency for this component.

Comentado [FWS6]: Is this relevant? Please delete.

All projects are reporting all mortalities via SPUT reporting regardless of how many.

1.0 INTRODUCTION

1.1 Project Background

Desert Sunlight 250, LLC and Desert Sunlight 300, LLC (collectively, Desert Sunlight) constructed and operates the Desert Sunlight Solar Farm Project (referred to in this report as "Project"), which consists of two main components: 1) a 550-megawatt (MW) photovoltaic (PV) generating facility; and 2) a 220-kilovolt (kV) generation interconnection (gen-tie) line. The Project comprises approximately 1,700 hectares (ha; 4,200 acres) of land administered by the Bureau of Land Management (BLM) six miles north of Desert Center in Riverside County, California (Figure 1).

1.2 Monitoring Plan Overview and Goals

A Bird and Bat Conservation Strategy (2014; “BBCS”) was prepared by the Project proponent in collaboration with the U.S. Fish and Wildlife Service (USFWS), California Department of Fish and Wildlife (CDFW), and BLM to guide comprehensive monitoring of impacts to birds and bats associated with operation of the Project. Final agency approval of the BBCS occurred in December 2014. Amendments to the sampling protocol along some portions of the Project fenceline were made by Desert Sunlight and approved by the BLM on February 11, 2015.

The BBCS details post-construction monitoring to be conducted and the data analysis and reporting processes that will be implemented by Desert Sunlight in collaboration with the USFWS, CDFW, and BLM. As identified in the BBCS, they are:

1. Estimate overall annual avian fatality rate and species composition associated with the Project infrastructure. This estimate will include mortality associated with solar arrays, overhead lines including the gen-tie line, perimeter fence and other features of the Project that may result in injury and fatality.
2. Determine whether there are spatial and temporal/seasonal patterns of mortality associated with project infrastructure (e.g., different fatality rates near panels on the edge of the arrays vs. the interior area of the arrays).
3. Provide information that will assist the BLM in consultation with the USFWS in understanding which species and potentially which regional populations are at risk.
4. Collect data in such a way that the BLM in consultation with the USFWS may make comparisons with other solar sites.

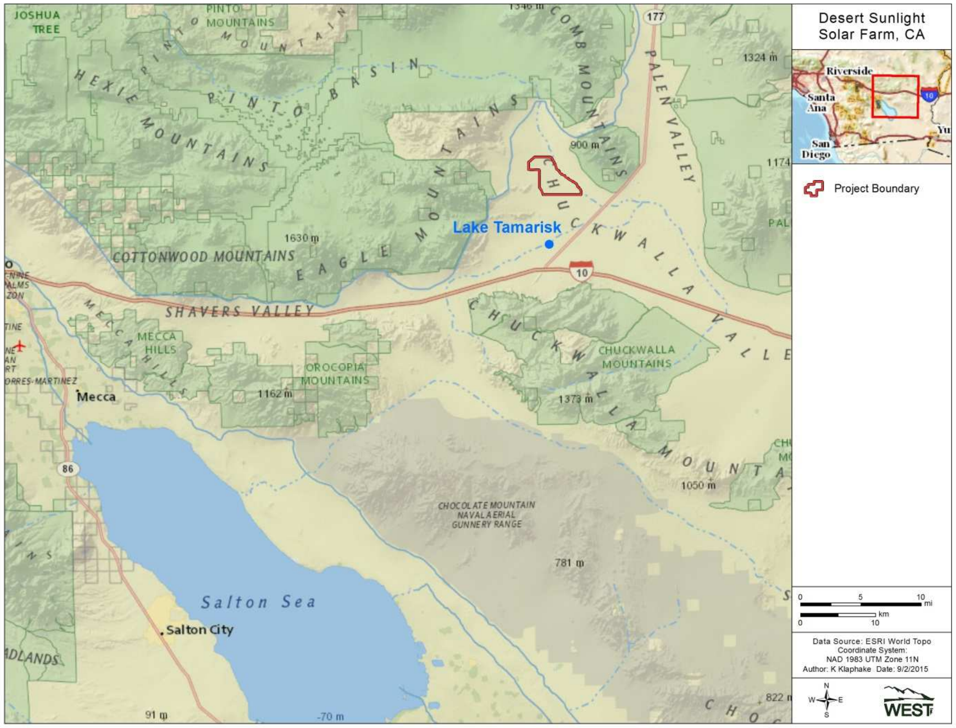

Figure 1. Desert Sunlight Solar Farm Project vicinity map, Riverside County, California.

1.3 Purpose of This Report

This report represents the second seasonal report for the first year of monitoring summarizing monitoring methods and results for avian and bat fatalities and injuries based on the procedures and requirements specified in the approved BBCS. This report and the other interim quarterly reports are considered preliminary summaries of data and information for the seasonal monitoring periods. Final information from all four quarterly monitoring periods will be included in a comprehensive final annual report. This report covers the period June 01 to August 30, 2015, or the 2015 summer season. For logistical reasons, fall monitoring began on Monday, August 31, 2015. All carcasses and injuries that were discovered by observers are referred to as "detections" in this report. As stated in the approved BBCS, this seasonal report includes the observed detections for likely diurnal, and likely nocturnal species, and for ecological guilds of interest (e.g., raptors, water-associated birds, passerines), for each of the facility types and suspected causes of death. Species composition of detections and the results of the bias trials are also reported. This report presents information related to the spatial distribution of detections, but no formal statistical analysis of the spatial distribution of carcasses will be conducted until the end of the monitoring year, given the limited data presently available.

2.0 METHODS

The BBCS describes the methods by which monitoring and certain analyses, including compilation of the overall fatality estimate, will occur. Below is an abridged description (see BBCS for detailed methods).

2.1 Standardized Carcass Searches

This section describes areas surveyed, the timing and frequency of searches, and the methods by which standardized searches were conducted to identify dead/injured birds and bats at the Project. Dead or injured birds and bats are called detections in this report to provide consistency in naming. This section also describes the methods for conducting carcass removal and searcher efficiency trials; how data were reported and analyzed; and the methods for producing fatality estimates for the Project.

2.1.1 *Areas Surveyed*

Standardized carcass searches were conducted at sampling units, which include the solar arrays (Table 1, 2; Figure 2); the "fenceline" defined as the perimeter fence for the Project (Table 1, Figure 2); and the gen-tie line (from the Project fence to the Red Bluff Substation on the south side of I-10; Table 1, Figure 3). Some overhead lines co-occur with solar arrays (medium voltage overhead lines [MVOH]). The MVOH were part of standardized carcass searches to the extent that they co-occured with solar arrays included in the sample (Table 2; Figure 2).

Table 1. Areas included in standardized carcass searches at the Desert Sunlight Solar Farm Project during summer (June 01 – August 30) 2015.

Project Component	Total Size	Units	% of Component Searched
Solar arrays	1045.9	Hectares	29.5[1]
Fence	16.7	Kilometers	99.0[2]
Gen-tie line	19.2	Kilometers	47.9[3]

[1] Percent area that was searched in summer 2015. Slightly less than 30% total because of unequally-sized arrays.

[2] 74.4% of the fence is fully accessible and surveyed following the standard protocol, while approximately 25% of the fence is surveyed from a distance. Fatality rates estimated for sections of the fence that are sampled were extrapolated to sections of the fence where the standard monitoring protocol cannot be used, as described in section 4.2.6 of the approved Desert Sunlight BBCS. A very short segment near the gate is not sampled due to restoration activities.

[3] 52.1% of the gen-tie will be sampled in 2016.

Comentado [FWS7]: Please describe how detectability is being handled for the 25% being surveyed from a distance.

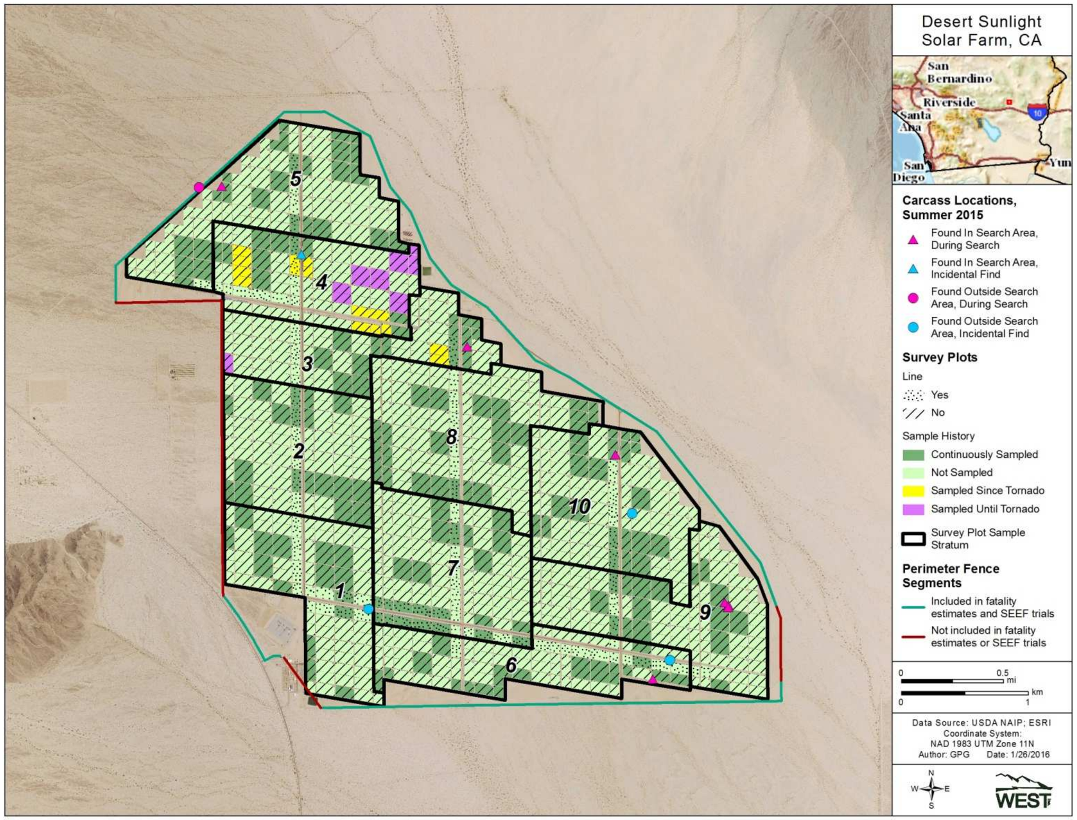

Figure 2. Areas of standardized searches and detections (those made during searches and those made incidental to operations and maintenance) at the solar field, fence, and overhead lines within the fence at Desert Sunlight Solar Farm Project during summer (June 01 – August 30) 2015.

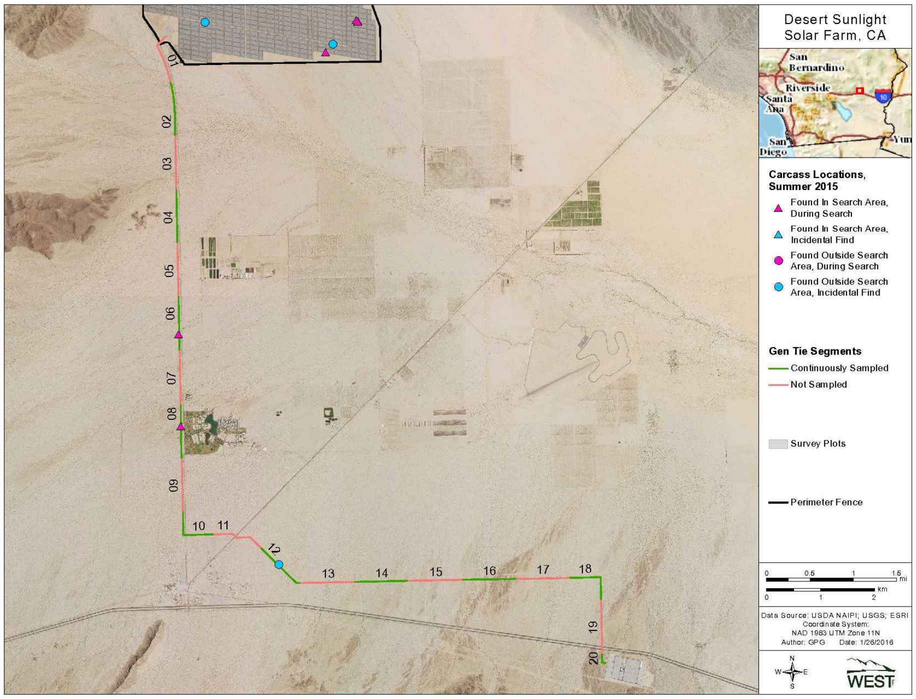

Figure 3. Areas of standardized searches and detections (those made during searches and those made incidental to operations and maintenance activities) along the generation tie line at the Desert Sunlight Solar Farm Project during summer (June 01 – August 30) 2015. Detailed maps of detections along the line are presented in Appendix A.

To ensure a balanced distribution of sample units in the solar field (defined as the collection of all photovoltaic [PV] solar panels), the entire field was divided into ten strata, and individual sampling units were randomly selected within each stratum to compose an approximately 30% sample. This sampling design ensures that units included in the sample were not spatially clumped within the solar field. The solar field consists of arrays of solar panels (referred to as a solar array) that are either 70-m or 140-m wide. The sample includes 133 of each type of array. There are 2,580 70-m rows, and 3,900 140-m rows in the sample.

2.1.1 *Search Frequency and Timing*

Standardized searches occurred during the summer survey season, which includes the period from June 01 through August 30, 2015. All project components included in standardized searches were surveyed four times during summer. All searches took place during daylight hours from ~~06:30~~ 05:40 to ~~17:00~~14:08.

Comentado [FWS8]: Please record and report data on the time of the surveys. This will help determine if the surveys can be used to predict nocturnal vs. diurnal mig behavior.

Raw data sheets and GIS files should be submitted with each report.

As specified in the approved Desert Sunlight BBCS, the average search interval for all Project components included in standardized carcass searches during summer was 21.0 days (median 21.0 days). Slight variation in search interval was anticipated due to weather and logistical delays.

Comentado [FWS9]: Please discuss the effect of the long search interval in relation to the carcass persistence trial data.

Table 2. Area and proportion of solar arrays that are and are not associated with overhead lines at the Desert Sunlight Solar Farm Project, Riverside County, CA.

	Line-associated[1]	Not line-associated	Proportion line-associated
Entire facility	89.4 ha	956.5 ha	0.09
Standardized searches	32.2 ha	291.0 ha	0.10

[1] Line-associated area was estimated as the area of any array that fell within the 30-m strip transect below the MVOH.

2.1.2 *Search Methods*

Standardized carcass searches were performed by BLM-approved biologists, in accordance with methods outlined in the BBCS.

Within the solar field, arrays of solar panels were surveyed by observers traveling on foot. A distance sampling approach was used, whereby biologists slowly walked a transect line along the ends of rows of solar panels in a direction perpendicular to the rows, searching ahead and to the side within the array for bird and bat detections. Biologists scanned out to a maximum perpendicular distance of approximately 70 m from the transect. Biologists carried binoculars to allow them to verify the presence of a detection versus rocks or vegetation. Once a detection was confirmed, the distance of the detection to the transect line was estimated using laser range finders. Each array included in the sample was searched by observers walking two transects – one on the west side and one on the east side of the array with observers looking toward the center of the array.

~~Once~~ As soon as a carcass was detected, it was photographed, and data were recorded according to specifications outlined in section 7.2.5 of the approved Desert Sunlight BBCS. Carcasses were then immediately retrieved from their location on the ground, labeled, and placed in a freezer on site.

Comentado [FWS10]: Please explain details about how/when the processing occurred in relation to when carcasses were detected.

Most (74.4%) of the length of fenceline (approximately 10 miles) was searched from a vehicle using the standard protocol (Figure 2). Biologists searched a 6-m wide strip transect centered on the fence from the inner perimeter. Travel speed was below five miles per hour (mph) while searching. Some sections along the fence cannot be driven close to the fence line. The fence line along the western edge of the Project is drivable but the road is approximately 15 m away from the fence and the road and fence are separated by a drainage ditch. The fence along this section is covered with a tan tarp and trees and shrubs have been planted to reduce visibility of the project from the west. Additions of vegetation and the tarp likely reduce potential for bird collision with the fence. This section of the fence was driven to document carcasses, but detections along this portion of the fence are not included in adjusted fatality estimates because detection rates are likely very low. As specified in section 4.2.6 in the approved Desert Sunlight BBCS, we assume that fatality rates are similar between the portion of fence that was searched and the portion that was not. A separate section of the fence in the southeastern corner of the Project cannot be driven because the eastern edge of the berm that bounded construction ponds is too narrow for a vehicle. Along this portion of the fence, the observer stopped at both north and south ends of the berm and used binoculars to search for carcasses. Finally, the road along a portion of the southwest fence line near the entrance gate is approximately 30 to 50 m from the road and is separated from the fence by an area that has recently undergone vegetation restoration. This area was eliminated from sampling. Fatality rates estimated for sections of the fence that were sampled were adjusted to account for the proportion of fence not sampled with the standard monitoring protocol, as specified in section 4.2.6 of the approved Desert Sunlight BBCS.

Comentado [FWS11]: The Service is still concerned that this section of the fence is not being adequately sampled. Mortality rates may be different along this section of the fence.

The gen-tie line was searched using a 30-m wide strip transect (i.e., 15 m of ground on either side of the overhead line). Sample units along the gen-tie line were chosen by dividing the total length of line from the Project fence south to the Red Bluff Substation just south of I-10 into 1-km segments. Thus, a 47.9% sample of the total length of the line was searched (Figure 3). Biologists slowly walked every other 1-km segment of the line, meandering the width of the strip transect, scanning for dead or injured birds or bats within 15 m (49.2 ft) of the overhead line.

For each detection, a suspected cause of death or injury was assigned based on evidence available from the detection, evidence available on Project infrastructure, and proximity of the detection to Project infrastructure. Detections that had evidence of scavenging and lacked evidence on Project infrastructure were assigned as “unknown” because it cannot be determined whether the event was caused by predation or interaction with project infrastructure. Detections that were intact (i.e., no evidence of scavenging) and located in close proximity to Project infrastructure (e.g., found directly beneath overhead lines) had a suspected cause of death attributed to the respective Project component. However, it should be noted that there is substantial uncertainty associated with cause of death assignments because no events were directly observed. Detections assigned to the “unknown” category were included in fatality estimates if they were located within standardized carcass search areas, and all detections made during the summer season are reported here.

Comentado [FWS12]: The Servicde disagrees with this assumption. If it’s under the line, the better assumption is that it was caused by the line and a scavenger subsequently discovered the carcass.

2.2 Carcass Persistence Trials

Carcass persistence trials were conducted throughout the summer period. Carcasses from three size classes (small [0-100 g], medium [101-999], and large [1000+ g]) were used for trials. The small size class comprised house sparrows (*Passer domesticus*) and 2-3 week old coturnix quail (*Coturnix coturnix*), the medium size class comprised rock pigeons (*Columba livia*), chukar (*Alectoris chukar*), and older coturnix quail, and the large size class comprised hen mallard (*Anas platyrhynchos*) and hen ring-necked pheasant (*Phasianus colchicus*).

2.2.1 *Carcass Persistence Data Collection*

To quantify carcass persistence rates, 15 small, 10 medium, and 5 large carcasses were randomly placed and monitored along the gen-tie line during summer 2015. Within the solar arrays and along the perimeter fence, the same numbers of each size category were placed, for a total of 60 carcass persistence trials at Desert Sunlight during the summer season, as specified in the approved Desert Sunlight BBCS. By placing carcasses inside (within arrays and along inner perimeter of the fence) and outside (along the gen-tie) the project fence, the possibility that there are different carcass persistence rates inside and outside the project fence is accounted for. Fifteen carcasses within the Project fence (within solar arrays and along the fence) were monitored using motion-triggered digital trail cameras, while the remaining carcasses were visited on foot, for 30 days or until the carcass had deteriorated to a condition at which it would no longer qualify as a documentable fatality. No carcasses along the gen-tie line were monitored with cameras because of theft and vandalism concerns. Carcasses without trail cameras were visited and photographed once per day for the first four days, and then every three to five days until the end of the monitoring period. To avoid training scavengers to recognize cameras as “feeding stations”, trail cameras were installed five days before specimens were placed, and two fake cameras without bias trial carcasses were also placed within the Project fence and periodically moved to new locations within the fence. Periodic ground-based checking of carcasses with trail cameras also occurred to guard against misleading indicators of carcass removal, such as wind blowing the carcass out of the camera’s field of view. To minimize potential bias caused by scavenger swamping (Smallwood 2007, Smallwood et al. 2010), carcass-persistence specimens were distributed across the entire Project, not just in areas subject to standard searches, and trials were initiated in smaller numbers on three different dates throughout the summer season.

Comentado [FWS13]: This number of carcasses is extremely low. The Service recommends increasing the number of trial carcasses to help reduce the confidence intervals on estimates.

Comentado [FWS14]: With such a low number of carcasses this is unlikely to be a problem.

2.2.2 *Estimating Carcass Persistence Times*

Carcass persistence trials were checked daily during the first ~~4~~four days and then every ~~3~~three to ~~5~~five days until the 30-day trial length was reached. Measurements of carcass persistence rates were subject to censoring. In this context, censoring refers to the instance when a value (e.g. days a carcass is present before being removed) may not be known exactly, but is known to be within a finite range. For example, suppose a carcass was checked on day 7 and was present, and was checked again on day 10, but was found to be missing. The exact time until removal is unknown; however, it is known that the carcass became unavailable at some point between 7 and 10 days. This carcass would be considered “interval censored”. Similarly, if a carcass lasts the entire 30-day trial period, that carcass is “right censored”— it is known that the carcass lasted at least 30 days, but it may have persisted longer. Because carcass persistence data were censored, persistence was analyzed using methods that can accommodate censored data and still produce unbiased estimates of the probability of persistence (Therneau 2015, Therneau and Grambsch 2000). It is beyond the scope of this document to provide statistical foundations of censored-data survival models but functions identical to those provided with the

Comentado [FWS15]: Please describe the interval that carcasses were checked. Is there a reason that they are not checked daily, particularly during the first week?

Comentado [FWS16]: Please clarify how censored data were analyzed and how the analytical methods affected the results. The referenced book is not available to the reader; please provide citation to the agencies. How does the method affect the effective search interval?

USGS-developed fatality estimator software (Huso et al 2012) ~~was~~ were used to fit survival models to the censored carcass persistence data, and some background is available in the documentation provided with that software.

The USGS software used to estimate carcass persistence calculates the period over which there is less than a 1% chance for a carcass to persist. The 'effective search interval' is defined as the shorter of the period during which there is less than a 1% probability that a carcass persists, and the actual search interval (Huso 2010). The probability of persistence is given for the effective search interval, and the probability that a carcass persists through the actual search interval is equal to p (persist through effective search interval) * effective search interval / actual search interval.

There were four distributions implemented in survival models used to estimate the probability a carcass is unscavenged and available to be found at the end of the search interval (*r*): exponential, Weibull, loglogistic, and lognormal. These four distributions exhibit varying degrees of flexibility in order to model a wide variety of distributions of persistence time. Akaike's Information Criterion adjusted for sample size (AICc; Akaike 1973) was used to rank the fit of each survival model with combinations of the covariates carcass size, Project component, season, and visibility, to observed carcass persistence data.

2.3 Searcher Efficiency Trials

Searcher efficiency trials were conducted throughout the summer period. Carcasses from three size classes (small, medium, and large) were used for trials. The small size class comprised house sparrows and 2-3 week old coturnix quail (*Coturnix coturnix*), the medium size class comprised rock pigeons, chukar, and older coturnix quail, and the large size class comprised hen mallards and hen ring-necked pheasants.

2.3.1 *Searcher Efficiency Data Collection*

Training of biologists on the Project-specific protocol and early assessments of habitat conditions within the solar arrays suggested that the amount of cobble present in the soil may be an important factor influencing searcher efficiency. To satisfy requirements regarding consideration of visibility class per the BBCS and address the influence of cobble cover on searcher efficiency, sample units in the solar arrays and along the gen-tie were stratified by cobble cover and assigned to one of two classes (<15% and >15% cobble cover). Classes were determined by making ocular estimates of cobble cover at each sample unit and then evaluating the frequency histogram of sample units across the range of estimated cobble cover (Figure 4). A natural break point was identified at 15% cobble cover, so the same value was chosen as the break point that defined the two cobble cover classes. ~~Thus,~~ For most seasons, i~~I~~n the solar arrays, two sets of searcher efficiency trials ~~were~~ will be conducted (one set in each cobble cover class; *n* for each class~~trial~~ = 15 small birds, 10 medium birds, and 5 large birds as agreed upon in section 7.4 of the approved Desert Sunlight BBCS). During summer 2015, all searcher efficiency trial carcasses were inadvertently placed in the low cobble cover class, precluding any tests of the effect of cobble cover class on searcher efficiency in the solar arrays. Additional trials will be conducted in the winter period in cobble to address this oversight and small sample

Comentado [FWS17]: The Service proposed larger sample sizes for carcass persistence and searcher efficiency trials. Hence, has this been evaluated as adequate to determine searcher efficiency for a single strata? Please provide justification for small sample size.

size. Along the gen-tie, visibility was expected to be related to vegetation and rock cover. Thus, searcher efficiency trials along the gen-tie occurred in two visibility classes (*n* for each class = 15 small birds, 10 medium birds, and 5 large birds (easy: ≥90% bare ground, vegetation <6” tall; and more difficult: <90% bare ground, vegetation ≥6” tall). Inadvertently, one large carcass was not placed and one extra small carcass was placed during summer, so total sample size for large carcasses along the gen-tie was nine, and for small carcasses was 31. Thirty searcher efficiency trial carcasses~~s~~ (*n* = 15 small birds, 10 medium birds, and 5 large birds) ~~occurred~~ were placed along the fence in the only visibility class present on the fence (easy visibility). Thus, during summer, a total of 150 searcher efficiency trials occurred at the Project. Locations for trials were chosen by taking a randomized sample of all locations included in standardized carcass searches.

Comentado [FWS18]: The terminology here is inconsistent with above. Each carcass counts as a trial or a trial consist of n carcasses?

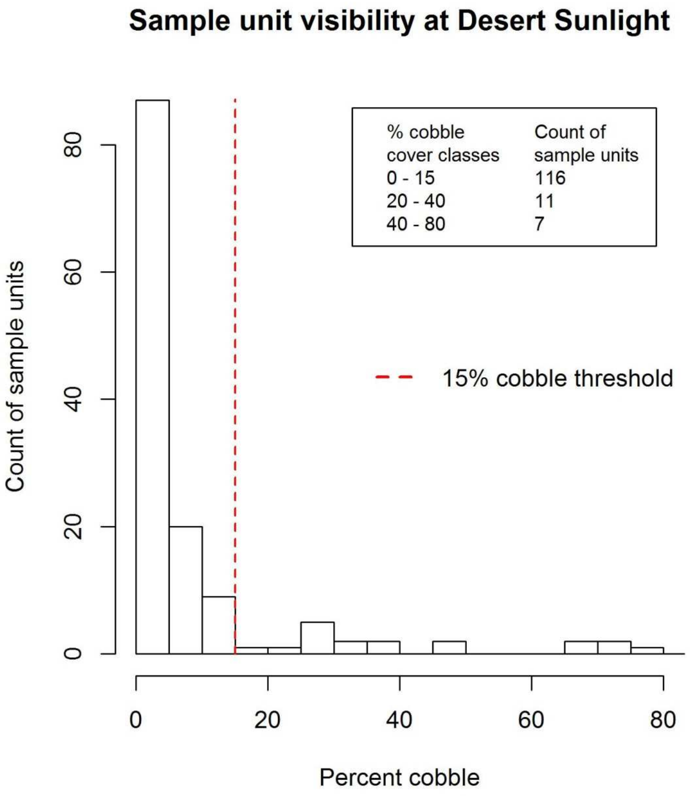

Figure 4. Frequency histogram of sample units (in the arrays only) at Desert Sunlight Solar Farm Project by estimates of cobble cover. Based on this distribution, each sample unit was assigned to one of two classes of cobble cover (<15%; >15%).

2.3.2 *Estimating Searcher Efficiency*

Comentado [FWS19]: Is searcher efficiency tested for each observer? Please provide these results along with an indication of variation in searcher efficiency across observers.

Searcher efficiency at Desert Sunlight was estimated separately for linear features (the project fence and the generation tie line), and the solar arrays, reflecting the different search methods used on arrays and linear features. For linear features, logistic regression models were fit to searcher efficiency data and AICc was used to compare models. Models including effects of carcass size (three classes), visibility (two classes; gen-tie only), and season were compared to each other and the null model. Model selection indicated that the ~~best~~ most supported model included main effects of Project component, carcass size, and season. Once the ~~best~~ most supported model was chosen and appropriate classes identified, searcher efficiency, or the proportion of carcasses detected, *p*, was calculated for each class using the following equation:

$$p = \frac{Number\ of\ Carcasses\ Observed}{Number\ of\ Carcasses\ Available}$$

The data for this analysis included all searcher efficiency trial carcasses from the summer 2015 season.

For the solar arrays, searcher efficiency was evaluated using a distance sampling approach (Buckland et al. 1993). Distance sampling assumes perfect detection on the transect line (at distance = 0), an assumption that is likely valid in the solar arrays given the relatively flat & vegetation-free nature of the soil surface. A curve is fitted to the observed carcass data that predicts probability of detection as a function of distance from the transect line. The mean value of this function over a specified distance, *w,* is equal to the average searcher efficiency for a transect of width *w*. The mean value of the detection curve is the integral of the detection function calculated between 0-m and the maximum survey distance (*w;* half the width of the solar array row), divided by the maximum survey distance:

$$p = \frac{\int_0^w f(x)dx}{w},$$

Con formato: Resaltar

where f(x) is the detection function evaluated at distance, *x*.

One departure in the methods used here, relative to the methods presented in Buckland et al. (1993), was that for this study the detection function was estimated using trial carcasses, which meant that there were both presence (detected) and absence (not detected) data available to fit the detection function (Figure 5). The availability of both presence and absence data means that the detection function can be estimated using only trial carcasses whose distribution is known. Therefore the detection function, the average searcher efficiency among the arrays and the final fatality estimate within the arrays are all insensitive to the spatial distribution of carcasses within individual arrays, and the overall searcher efficiency estimate is valid even if the distribution of carcasses among the arrays is not uniform.

Distances of trial carcasses (trials both found and missed) from the transect line were used to fit a half-normal detection function for searches among the arrays (Figure 5). The half-normal detection function is a commonly used function for distance sampling surveys (Buckland et al. 1993). The detection function was fit with and without covariates (carcass size, season, ~~visibility index,~~ or no covariates) and AICc indicated that the ~~best~~ most supported among these models included only carcass size as a covariate.

Comentado [FWS20]: Please provide an analysis that the sample size is adequate to detect a difference between visibility categories. This result seems to be an artifact of the low sample size.

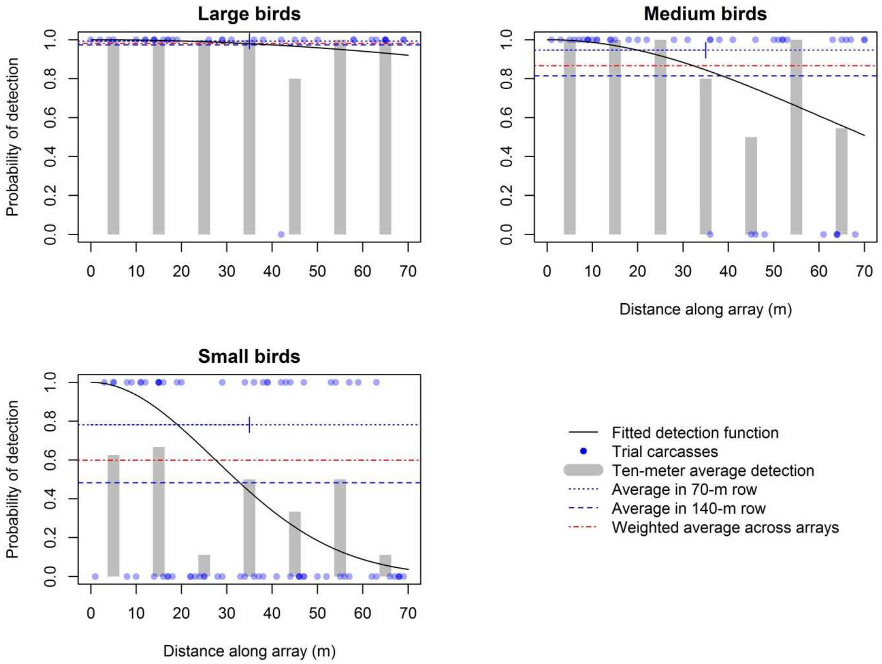

Figure 5. Estimated detection probabilities for bird carcasses by size class across all available seasons used for ~~during~~ summer (June 01 – August 30) 2015 fatality estimates at the Desert Sunlight Solar Farm Project, Riverside County, California. Distance sampling was used when searching solar arrays only. Average probability of detection over 70-m (arrays relying on a 35-m viewshed) and 140-m (arrays relying on a 70-m viewshed) panel rows in solar arrays are presented.

Comentado [FWS21]: Please explain the dots in the figure. The number of dots is greater than the number of trial carcasses.

Because the solar arrays were surveyed by searchers who walked down both sides of the rows of panels, the width of the search transect was specified as half the width of the rows of panels. For larger birds, there is almost certainly a non-zero detection probability beyond this distance but the bias that occurs by ignoring this non-zero detection probability is conservative (i.e. the searcher efficiency is underestimated). Some solar arrays have row widths of 70 m (search transect width of 35 m) and some have row widths of 140 m (search transect width of 70 m). The weighted average searcher efficiency is calculated based on the number of panel rows of each length in the survey sample:

$$p_{weighted\ average} = \frac{n_{70}}{n} \times \frac{\int_0^{35} f(x)dx}{35} \cancel{\int_0^{35} f(x)dx} + \frac{n_{140}}{n} \times \frac{\int_0^{70} f(x)dx}{70} \cancel{\int_0^{70} f(x)dx},$$

Comentado [FWS22]: The denominator (w) from the equation for p (from page 12 equation) is missing from this equation. Is this a typo or was the equation modified for a reason? If so, please explain.

where $n_{70} = 2580$ is the number of 70-m rows in the sample, $n_{140} = 4020$ is the number of 140-m rows in the sample, and *n* is the total number of rows in the sample. Searcher efficiency was higher for the arrays with a width of 70 m, and overall searcher efficiency was estimated as a weighted average based on the proportions of 70-m arrays and 140-m arrays in the sample units.

Comentado [FWS23]: Please provide the values for n_{70} and n_{140}.

2.4 Fatality Estimator

Fatality rate estimation is a complex task due to several variables inherent to every fatality monitoring study. Carcasses may persist for variable amounts of time due to local scavenger activity or environmental conditions leading to carcass degradation over time. Carcasses and feather spots are also detected with varying levels of success based on carcass characteristics and ground cover (e.g., vegetated areas underneath the gen-tie line versus cleared areas beneath solar panels). For these reasons, it is generally inappropriate to draw conclusions based on the raw number of fatalities alone. The desire to estimate fatalities given these variables has driven the development of several statistical methods for estimating fatalities (e.g., Smallwood 2007, Huso 2010, Korner-Nievergelt 2011). All of these fatality estimation methods share a similar underlying model. Generally, the fatality estimation for a given site may be written as:

$$F=C/rp,$$

where *F* is the total number of fatalities, *C* is the number fatalities detected and included in fatality estimation, *r* is the probability a carcass is ~~unscavenged~~ not scavenged and available to be found at the end of the search interval, and *p* is the probability of detecting a carcass (Huso 2010)–.– Huso (2010) describes the use of a binomial model to estimate the probability of carcass detection; in the present study, the binomial carcass detection model was used to calculate fatalities at project linear features (fence, overhead lines), and the weighted average probability of detection based on distance sampling (described above) was used to estimate probability of detection within the solar arrays.~~where the probability of detecting a carcass at solar arrays is the weighted average from above.~~

Comentado [FWS24]: Is this the weighted average probability from above?

All fatality estimates were calculated using the Huso estimator (modified to accommodate the distance-sampling based estimate of searcher efficiency in the solar arrays), as well as 90% confidence using bootstrapping (Manly 1997). Bootstrapping is a computer simulation technique that is useful for calculating point estimates, variances, and confidence intervals for complicated test statistics. A total of 1,000 bootstrap replicates ~~were~~ was used for each of searcher efficiency (*p*), probability of a carcass persisting to the next search ($\hat{r}$), adjusted search interval and observed fatalities. From these bootstrap samples, the probability of available and detected was calculated and applied to the bootstrapped observed fata~~t~~lities. The lower 5th and upper 95th

Comentado [FWS25]: Please describe what was bootstrapped and how. The table in the appendix is difficult to understand without a better understanding of the bootstrapping methods.

percentiles of the 1,000 bootstrap estimates provide estimates of the lower limit and upper limit of an approximate 90% confidence interval on all estimates.

2.5 Incidental Reporting

Some detections were outside standardized search areas, or were within search areas but not observed during standardized searches. Such detections were found by WEST avian biologists and operational personnel and were considered “incidental” detections. When found by operational personnel, these detections were reported to WEST avian biologists for documentation. Data on incidental detections are reported here, as well as in the Desert Sunlight SPUT Avian Injury and Mortality Report Forms June – August 2015. All detections made in search areas during the reporting period were included in fatality estimates, regardless of whether they were detected incidentally or during searches.

3.0 MONITORING RESULTS

3.1 Summary of Avian Detections

During summer 2015, a total of 15 avian detections (including incidentals) of 11 identified species were recorded (Table 3). The most common identified species was common raven (*Corvus corax*) with three detections. Most detections (n = 11, or 73.3% of total detections) occurred in the solar arrays (Figures 2 and 3; Tables 4, 5, and 6). Ten (66.7%) detections were made during standardized carcass searches and five (33.3%) were documented as incidentals. No bats were detected during the summer season. For fresh carcasses, body weights and weather conditions the preceding nights are described in Appendix B.

Table 3. Number of individual bird detections, by species, during summer (June 01 – August 30) 2015 at the Desert Sunlight Solar Farm Project, Riverside County, California. LA = line-associated; NLA = non-line associated.

Common Name	Scientific Name	Migration Behavior*	Guild	LA Solar Array	NLA Solar Array	Fence	Gen-tie Line	Total

Total				**2**	**9**	**1**	**3**	**15**

* See literature cited for migration behavior references; information for most species was taken from the respective species accounts found in Birds of North America (BNA) Online (http://bna.birds.cornell.edu/bna/); where information on migration behavior was lacking in BNA accounts, Newton (2008) or Murray (2004) were used.

Comentado [FWS26]: Aechmophorus species or a different genus?

Table 4. Total avian detections by Project component and detection category during summer (June 01 – August 30) 2015 at the Desert Sunlight Solar Farm Project, Riverside County, California. Only carcasses found within search areas were included in fatality estimates.

	Inside carcass search area		Outside carcass search area	
Project Component	**Carcass search**	**Incidental**	**Carcass search**	**Incidental**
Fence	0	0	1	0
O&M Building	0	0	0	0
Gen-tie line	2	0	0	1
Solar arrays				
Line-associated	0	0	0	2
Non-line associated	7	1	0	1

Table 5. Total avian detections (including incidentals) by Project component and suspected cause of death during summer (June 01 – August 30) 2015 at the Desert Sunlight Solar Farm Project, Riverside County, California.

	Suspected Cause of Death*				
Project Component	**Collision**	**Predation**	**Other**	**Unknown**	**Percent of Total**
Fence	0	0	1	0	6.7
O&M building	0	0	0	0	0
Gen-tie line	2	0	1	0	20
Solar arrays					
Line-associated	1	0	1	0	13.3
Non-line associated	1	0	5	3	60
Percent of Total	**26.7**	**0**	**53.3**	**20.0**	**100.0**

* Suspected cause of death was assigned based on evidence available on the detection, evidence available on Project infrastructure, and proximity of detection to Project infrastructure. Detections that had evidence of scavenging and lacked evidence on Project infrastructure were assigned as "unknown" because it can't be determined whether the event was caused by predation or interaction with project infrastructure. Detections that were intact (i.e., no evidence of scavenging) and located in close proximity to Project infrastructure (e.g., found directly beneath overhead lines) had a suspected cause of death attributed to the respective Project component. However, in the absence of a completed necropsy, there is ~~substantial~~ some uncertainty associated with cause of death assignments because no events were directly observed.

Comentado [FWS27]: Was proximity to project features evaluated? Please describe how this information was utilized. Proximity distances may provide insights into which features may pose the greatest risks.

Comentado [FWS28]: Since scavenger rates are so high, this definition too easily categorizes carcasses as unknown. Low levels of scavenging should not exclude birds from a more thoughtful evaluation of the cause of the mortality. Other criteria should be considered, including patterns of disturbed dust on solar panels, proximity to a feature with collision risk. Such a blanket categorization, probably masks useful information.

3.2 Temporal Patterns of Avian Detections

The number of detections recorded daily during the reporting period ranged from zero to three (Figure 6). One detection was found per day with the exception of June 24 when three detections occurred. The number of detections per day represents those discovered during standardized carcass searches and incidentally.

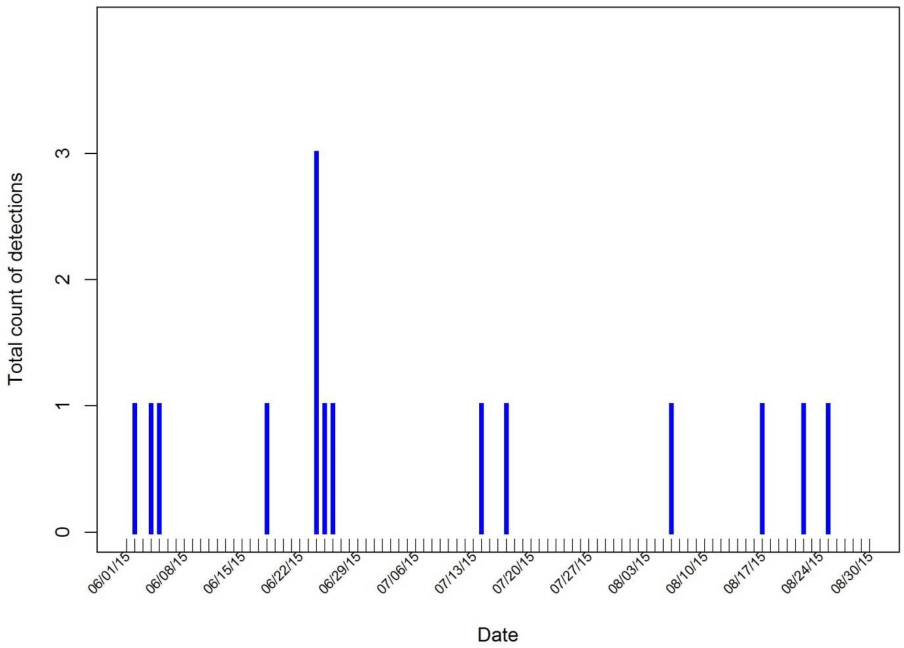

Figure 6. Total number of detections by date during summer (June 01 – August 30) 2015 at the Desert Sunlight Solar Farm Project, Riverside County, California.

3.3 Spatial Distribution of Avian Detections

Comentado [FWS29]: Spatial distribution of different taxonomic groups should be discussed, particularly as more data come in.

3.3.1 *Detections by Project Component*

During the reporting period, detections were documented from the solar arrays, the northern section of the perimeter fence, and the gen-tie line; no detections occurred at the O&M building (Tables 3, 4, and 5). Of the 11 detections within the solar arrays, 18.2% (2) were associated either with overhead lines or arrays that co-occurred with overhead lines.

3.3.2 *Feather Spot Detections*

Five (33.3%) of the 15 detections consisted only of feather spots. Along the gen-tie, one of three detections (33.3%) was a feather spot. No detections along the fence were a feather spot. Four of 11 detections (36.4%) in the solar arrays were feather spots.

3.4 Detections of Injured Birds

No injured birds were detected during the summer 2015 season.

3.5 Summary of Bat Detections

No bats were detected during the summer 2015 season.

3.6 Carcass Persistence Trials

Data from carcass persistence trials were available from late winter, spring, and summer at the solar field and gen-tie line (n = 154 total). Based on carcass persistence data from late winter, spring, and summer 2015, survival models were compared for relative quality using the corrected AICc score, as suggested in Huso (2010). The AICc score provides a relative measure of model fit and parsimony among a selection of candidate models, and provides a framework for testing hypotheses regarding which factors contribute to carcass persistence rates. Carcass size was tested as a potentially important variable, as larger carcasses tend to persist longer ~~and~~ than ~~may be more likely to leave feather spots which persist for long durations~~, ~~whereas~~ smaller carcasses ~~may be more likely to be completely removed~~. Project component (solar arrays/fence, generation-tie line) was also included as a potentially important variable, as was season.

The model with lowest AICc score is typically chosen as the ~~"best"~~ model with the most empirical support relative to other models tested; however, any model within two AICc points of the ~~best~~ model with the lowest score is considered competitive ~~with the best model~~ (Burnham and Anderson 2004). The ~~best~~ most supported model included main effects of season, carcass size, Project component, and interactions of Project component × season and Project component × size with a Weibull-distributed removal time. Given the main effect of season, further modeling efforts were restricted to data collected in summer only. The ~~best~~ most supported model using only the summer data suggested an interaction between carcass size and Project component. Estimates of carcass removal time and persistence probabilities are reported in Table 6 from the ~~best~~ most supported model, and estimates of proportion of carcasses remaining as a function of days since carcass placement are provided in Figure 7. The difference in carcass removal times between Project components is because scavengers likely occur in higher densities outside the perimeter fence.

Table 6. Mean carcass removal time and probability of a carcass persisting through the effective search interval (5.8 days) during the summer season (June 01 – August 30) at the Desert Sunlight Solar Farm Project, Riverside County, California.

Carcass size	Project component	Mean removal time (days)	Median removal time (days)	Probability of persistence
Small	Arrays/fence	15.5~~3~~	11.5	0.63
Small	~~Overhead~~ Gen-t~~T~~ie lines	1.37	0.5	0.22
Medium	Arrays/fence	19.2	22.5	0.73
Medium	~~Overhead~~ Gen-t~~T~~ie lines	14.8~~75~~	15.5	0.60
Large	Arrays/fence	-*	-*	1.00
Large	~~Overhead~~ Gen-t~~T~~ie lines	0.9	0.5	0.22

Comentado [FWS30]: This is not clear. Are you suggesting that feather spots from large carcasses last longer than feather spots from small carcasses? Or are you suggesting that large carcasses are more likely to produce feather spots than small carcasses and feather spots in general (large or small) persist for long durations? Please clarify and provide a rationale for the assertion and describe how it might affect the analysis.

Comentado [FWS31]: Is there enough data to do a good analysis?

Comentado [FWS32]: Please include the timeframe for the persistence trails for ease of reference (30 days?).

Comentado [FWS33]: This looks like there may be an effect on persistence time from being outside the fence. This may be due to differences in the scavenger community. Was this tested?

Comentado [FWS34]: This is the Gen-Tie, right? Better to refer to this as the Gen-Tie to distinguish it from the internal overhaed lines above the panels.

* Mean and median removal time was not estimated because no removal was observed for large carcasses within the solar field.

Comentado [FWS35]: The y-axis is cut off at 0.5. This obscures data for small and med bird size categories. Please provide the Figure with a y-axis range from 0.0-1.0.

3.7 Searcher Efficiency Trials

During the reporting period, a total of 150 searcher efficiency trials were placed at the Project. Most trials were available to be found, but some disappeared before or during the trial. Overall, 60 trials were placed in the solar arrays and 44 were available to be found; 30 trials were placed along the perimeter fence (inner perimeter only) and 30 were available to be found; and 60 trials were placed along the gen-tie line and 55 were available to be found. Searcher efficiency trials were conducted on each observer in approximate proportion to the number of searches they conducted at the Project, as follows: Sarah Nichols (number of trials available to be found: 84); Jennifer Johnson (67), and Pam Bullard (5).

Comentado [FWS36]: How was this broken down by visibility categories and size classes? See Appendix C?

In the solar arrays, the model that included an effect of carcass size was chosen as the ~~best~~ most supported model to estimate searcher efficiency. Thus, the data used to produce the following estimates of searcher efficiency include trials available to be found during February, spring, and summer (n = 180). Within the solar arrays, searcher efficiency was: 60.0% for small birds, 86.6% for medium birds, and 98.1% for large birds (Figure 5).

For linear Project components, the model that included an effect of carcass size, Project component, and season was chosen as the ~~best~~ most supported model to estimate searcher efficiency. Thus, the data used to produce the following estimates of searcher efficiency include trials available to be found during summer only along the fence (n = 30) and the overhead lines (n = 55). Along the fence, searcher efficiency ranged from 87.5% to 100% depending on carcass size class. Along overhead lines, searcher efficiency ranged from 43.5% to 100%. Detailed estimates of searcher efficiency estimates specific to each component and carcass size are reported in Appendix C.

3.8 Fatality Estimates

Fatality estimates were calculated separately for each component (solar arrays, fence, and overhead lines). Ultimately, five detections were excluded from the fatality analysis because they were found outside standardized search areas. All 15 detections made during summer are reported in Table 3. Detections used in the analysis, ~~and~~ bias corrections, summer fatality estimates, and 90% confidence intervals for summer fatality estimates are detailed in Appendix C.

Comentado [FWS37]: Please provide an additional summary tables with the following information for each component and for the entire facility: carcasses detected, estimated fatalities; 90% CI. An additional table with the same information for each size category is also requested.

Table 7. Status of detections during the summer (June 01 – August 30) 2015 season at the Desert Sunlight Solar Farm Project, Riverside County, California. All detections outside the search area were excluded from the fatality analysis, regardless of whether they occurred during a standardized carcass search or incidentally.

	Carcass search	**Incidental detection**	***Pushed to next season's fatality estimate**	***Pulled from previous season's fatality estimate**
Inside search area	9	1	0	0
Outside search area	1	4	0	0

* Incidental detections occurring after the last standardized carcass search in a season are considered for inclusion in the fatality analysis for the following season. This is consistent with the assumption we make throughout the monitoring seasons; that carcasses found incidentally would have been available to be found on the next scheduled search. This assumption may result in some carcasses found during one season but considered in the following season's fatality analysis. Once a carcass has been moved to a different season's analysis it is still subject to the same criteria for inclusion or exclusion based on location (in versus out of a searched area) and carcass age (greater than versus less than the search interval).

During summer 2015, there were an estimated total 148 carcasses (90% CI: 10 – 365) at the Project. Of these, 44 carcasses (27.5%; 90% CI: 8 – 64) were estimated for the solar arrays and 104 carcasses (66.9%; 90% CI: 2 – 339) were estimated for the gen-tie line. While we are required to report the gen-tie estimates per the approved BBCS, these estimates are not reliable due to the high rates of scavenging that were observed during the limited trials at the gen-tie and the low number of carcasses detected (n = 2 in the fatality analysis). No carcasses were estimated for the perimeter fenceline because there were no detections made along the fence. All of these estimates should be interpreted with caution because variance estimates are in general unreliable when carcass counts are low (< 5 per category). ~~Other projects (e.g. Ivanpah) are not reporting estimates when carcass counts are less than or equal to five. However, t~~The TAG has asked for both the estimates and confidence intervals for this project with the appropriate caveat added. There were an estimated ~~0.0~~17 fatalities per 1000 acres (within the solar field only; 44 estimated carcasses/2,585 acres) and an estimated 0.08 fatalities per nameplate MW (44 estimated carcasses/550 MW) within the solar field. A complete list of estimates for each Project component and carcass size class with confidence intervals is presented in Appendix C.

Comentado [FWS38]: The Service continues to recommend 95% CI, but even at 90% the CI is still too wide to be useful.

Comentado [FWS39]: Given the size of utility scale projects "per 1000 acres seems more appropriate.

4.0 DISCUSSION

The 2015 summer season represented the second full season of standardized monitoring at Desert Sunlight per the BBCS. Searcher efficiency trials and carcass removal trials were conducted concurrently at the solar arrays, fencelines, and along the gen-tie line. Data from these trials were used to produce fatality estimates adjusted for searcher efficiency and carcass persistence bias. Although these estimates were produced from a statistically robust sample, only limited inference may be drawn from two seasons of data. These results should be considered preliminary because estimating carcass persistence, searcher efficiency, and adjusted numbers of fatalities within each season represents information based on a limited sample size. As more data are collected throughout the monitoring year (and additional quality assurance/quality control measures occur, for example characterizing feather spots to species or size class), data from all seasons may be pooled. At that time, data will be tested for seasonal differences retrospectively, but because seasonal estimates will be produced from the much larger annual data set, they may differ from what is reported here because they are based on a larger, more informative sample.

4.1 Carcass Persistence and Searcher Efficiency Trials

The degree to which carcasses persist on the landscape depends on a variety of factors reflecting seasonal and inter-annual variation in habitat, climate, and the scavenger community. The composition and activity patterns of the scavenger community often vary seasonally as birds migrate, new juvenile birds and mammals join the local population, and mammalian scavengers variably hibernate or estivate. The scavenger community may also vary substantially from year to year because of variation in annual reproduction and survival related to changes in landscape condition. Climatic conditions that vary seasonally and annually also may contribute to variation in carcass decay and removal rates due to variation in temperatures, solar insolation, wind patterns, and the frequency of flooding events. Thus, rates of carcass persistence reported here should be interpreted cautiously as they may change over the coming months.

Fatality estimates are influenced by the relationship between carcass removal dynamics and search intervals. In practical terms, longer search intervals reduce average probability that a carcass persists until the next search. In terms of the analysis, this can manifest as a lower probability of persistence through the effective search interval, or an effective search interval that is shorter than the nominal search interval. In either case, the adjustment to carcass counts due to carcass removal dynamics is calculated as

$$\frac{length\ of\ effective\ search\ interval}{\begin{array}{c}length\ of\ nominal\ search\ interval * average\ probability\ of\ persistence\\ \text{-}through\ the\ effective\ search\ interval\end{array}}$$

The adjustment to estimated fatality for carcass removal increases with longer search intervals, and the variance in the estimate may increase, also.

Searcher efficiency was influenced by Project component, carcass size, and season. In the solar arrays, searcher efficiency was high (> 0.5) for all carcass size classes and this is likely influenced by the limited vegetation cover beneath solar panels. Beneath the gen-tie line, vegetation cover is higher in some portions of the strip transects, but results reported here support the hypothesis that visibility class is not a factor in searcher efficiency along the lines during summer. Placement of trial carcasses in both difficult and easy visibility classes ensures that the adjustment due to searcher efficiency accounts for both visibility classes, even if there is a real difference in searcher efficiency that cannot be detected with the trial data.

Comentado [FWS40]: Given the low number of trial carcasses, you can detect a difference between visibility classes.

For the current analysis, searcher efficiency in the solar arrays was assumed to be ~~best~~ predicted by a half-normal distribution. For future analyses, AICc will be used to compare and choose the ~~best~~ most supported among multiple detection functions.

4.2 Distribution of Fatalities and Fatality Estimates

The number of detections was more or less evenly distributed across the summer season, and there were no clear associations between number of detections and date. Given the small number of detections overall, it is premature to draw any conclusions about the spatial distribution of carcasses.

Composition of detections during summer 2015 included eight avian guilds. Corvids comprised the majority of detections (n = 3): there were two detections each within the doves/pigeons, rails/coots, and waterbirds/waterfowl guilds. No bats have been detected since monitoring began at the Project.

Detections attributed to an unknown cause accounted for 20.0% of all detections (68% of which were feather spots) during the reporting period, and all those attributed to an unknown cause were found in the solar arrays. Of the 11 detections made in the solar arrays, 36.4% were feather spots. Determining a cause of mortality from a feather spot is challenging because there is rarely visible evidence available on which to determine a cause of death. Thus, feather spots with an unknown cause of mortality could be encountered anywhere birds occur, and an unknown cause of a sizeable proportion of the carcasses is not unique to the Project. Further, game cameras trained on carcasses for carcass persistence trials at the Project have documented multiple feather spots originating from a single trial carcass. Ravens and turkey vultures, and possibly roadrunners, dislodge feathers from their attachment to the skin of carcasses during the scavenging process. There are a very large number of potential feather spots present on a single bird carcass (because a feather spot is defined as at least two or more primary flight feathers, at least five or more tail feathers, or two primaries within five m (16.4 ft) or less of each other, or a total of 10 or more feathers of any type concentrated together in an area of three square m). T~~t~~he relatively large proportion of feather spots (33.3%) among the detections for the Project as a whole may inflate the fatality estimate when unknown cause detections are included based on the potential for multiple feather spots resulting from one

Comentado [FWS41]: What fraction of these unknown detections are feather spots?

Comentado [FWS42]: We don't agree with this statement. This is unknown. Feather spots may be more mobile, but as far as I know there have been no studies on whether they "multiply" and cause bias. If there has, please provide a reference. It is possible that feather spots could accumulate along fences, but in general, they are just as likely to migrate into a survey area as they are to leave. If this is a significant problem, then I recommend shorter search intervals and more complete coverage of the project site.

fatality, feather spots resulting from predation not associated with the facility, or other causes. However, feather spots are included in the analysis here to provide a more conservative estimate of fatality.

OVERVIEW

A draft *Bird and Bat Fatality Monitoring Plan for the Desert Sunlight Solar Farm* ("Plan") was prepared by H.T. Harvey and Associates and presented to the Renewable Energy Action Team (REAT), including representatives from the Bureau of Land Management (BLM), United States Fish and Wildlife Service (USFWS) and the California Department of Fish and Wildlife (CDFW); in December 2013. While the details of this plan are still being discussed and a final version has yet to be accepted, the following goals remain consistent:

1. Calculate bird and bat fatality rates for the project and for individual species of concern.
2. What is the composition of fatalities in relation to breeding, migrating, wintering and fully resident species?
3. Do estimated fatality rates vary within the project site in relation to site characteristics, weather patterns, seasonally, or among years?
4. How do the calculated rates compare to those documented for existing projects in similar landscapes with similar species composition and use?

Specific objectives have been outlined to meet the goals of this Plan:

1. Conduct fatality searches throughout the year according to a spatial and temporal sampling plan that provides representative and statistically sound coverage of the solar arrays and associated interrelated and interdependent features.
2. Conduct statistically sound assessments to quantify and evaluate searcher efficiency and support calculations of adjusted fatality rates that account for variation in searcher efficiency.
3. Conduct statistically sound assessments to quantify and evaluate carcass removal rates (i.e. removal/ destruction of carcasses by scavengers, decay or other abiotic factors) and support calculations of adjusted fatality rates that account for relevant spatial and temporal variation in carcass removal rates and variation in removal rates related to carcass size classes.
4. Use current scientifically validated and accepted methods for calculating fatality rates adjusted for searcher-efficiency, carcass removal rates and spatial and temporal sampling intensity.

This document outlines a planned methodology to address objective 3 above, Carcass Removal Assessment

METHODOLOGY

Thirty non-native bird species of three different size classes (ten of each) will be randomly distributed within the survey area. A remote trail camera will accompany each placement and be used to determine: cause of removal (scavenger species or abiotic factor), date of removal and time of removal. Cautionary measures (described below) will be taken to minimize scavenger bias and avoid scavenger swamping. Trial monitoring will consist of a 30-day period for each carcass placement and upon conclusion of the monitoring period, each trial specimen will be classified into one of the following categories based its physical persistence and detectability:

Intact: Whole and unscavenged other than by insects

Scavenged/ depredated: Carcass present but incomplete, dismembered or flesh removed

Feather Spot: Carcass scavenged and removed, but ten or more feathers remain to qualify as a detectable fatality

Removed: Not enough remains to be considered a detectable fatality

Game Cameras

Thirty game cameras will be placed at randomized carcass locations within the Sample Area at least five-days in advance of the trial period in an effort to reduce the possibility that potential scavengers will form an association between cameras and a food subsidy. Cameras will remain in place, even after carcasses have been removed, until the end of the trial period. *Wildgame Innovations LO8* (eight megapixel) cameras will be powered by external battery packs to help ensure trouble-free operations over the monitoring period.

Carcass Placements

The placement of trial carcasses will be randomized within the Sample Area. The Sample Area will consist of primary project components that will be the focus of fatality surveys including: solar arrays, perimeter fence and overhead power lines. Other project areas, such as: retention basins, onsite sub-station and temporary water storage ponds, are not included as part of the Sample Area since focused fatality surveys will not take place within these project features. Areas of active construction, including main access roads, are not included in the Sample Area due to the presence of uncontrolled variables that will not exist once the project enters into a fully-operational phase.

Randomizing Carcass Placements

The methodology described for Avian Carcass Surveys by the draft *Bird and Bat Fatality Monitoring Plan for the Desert Sunlight Solar Farm* is based on the assumption that avian fatalities are random within the Sample Area. The placement of trial specimens for carcass removal assessments is based on the same assumptions used for carcass surveys. Trial specimens were randomly placed using a spatially balanced sampling routine. Areas of primary project components, including solar modules and perimeter fence, were identified in a GIS and an inclusion probability for each was created based on the relative area of each primary project component within the Sample Area. In the case of the linear perimeter fence, an interior buffer distance of 35 meters was applied. Using this approach, thirty carcasses, ten of each size class, will be randomly placed within the Sample Area

Figure 1 depicts randomized trial specimen locations within the Sample Area (energized zones).

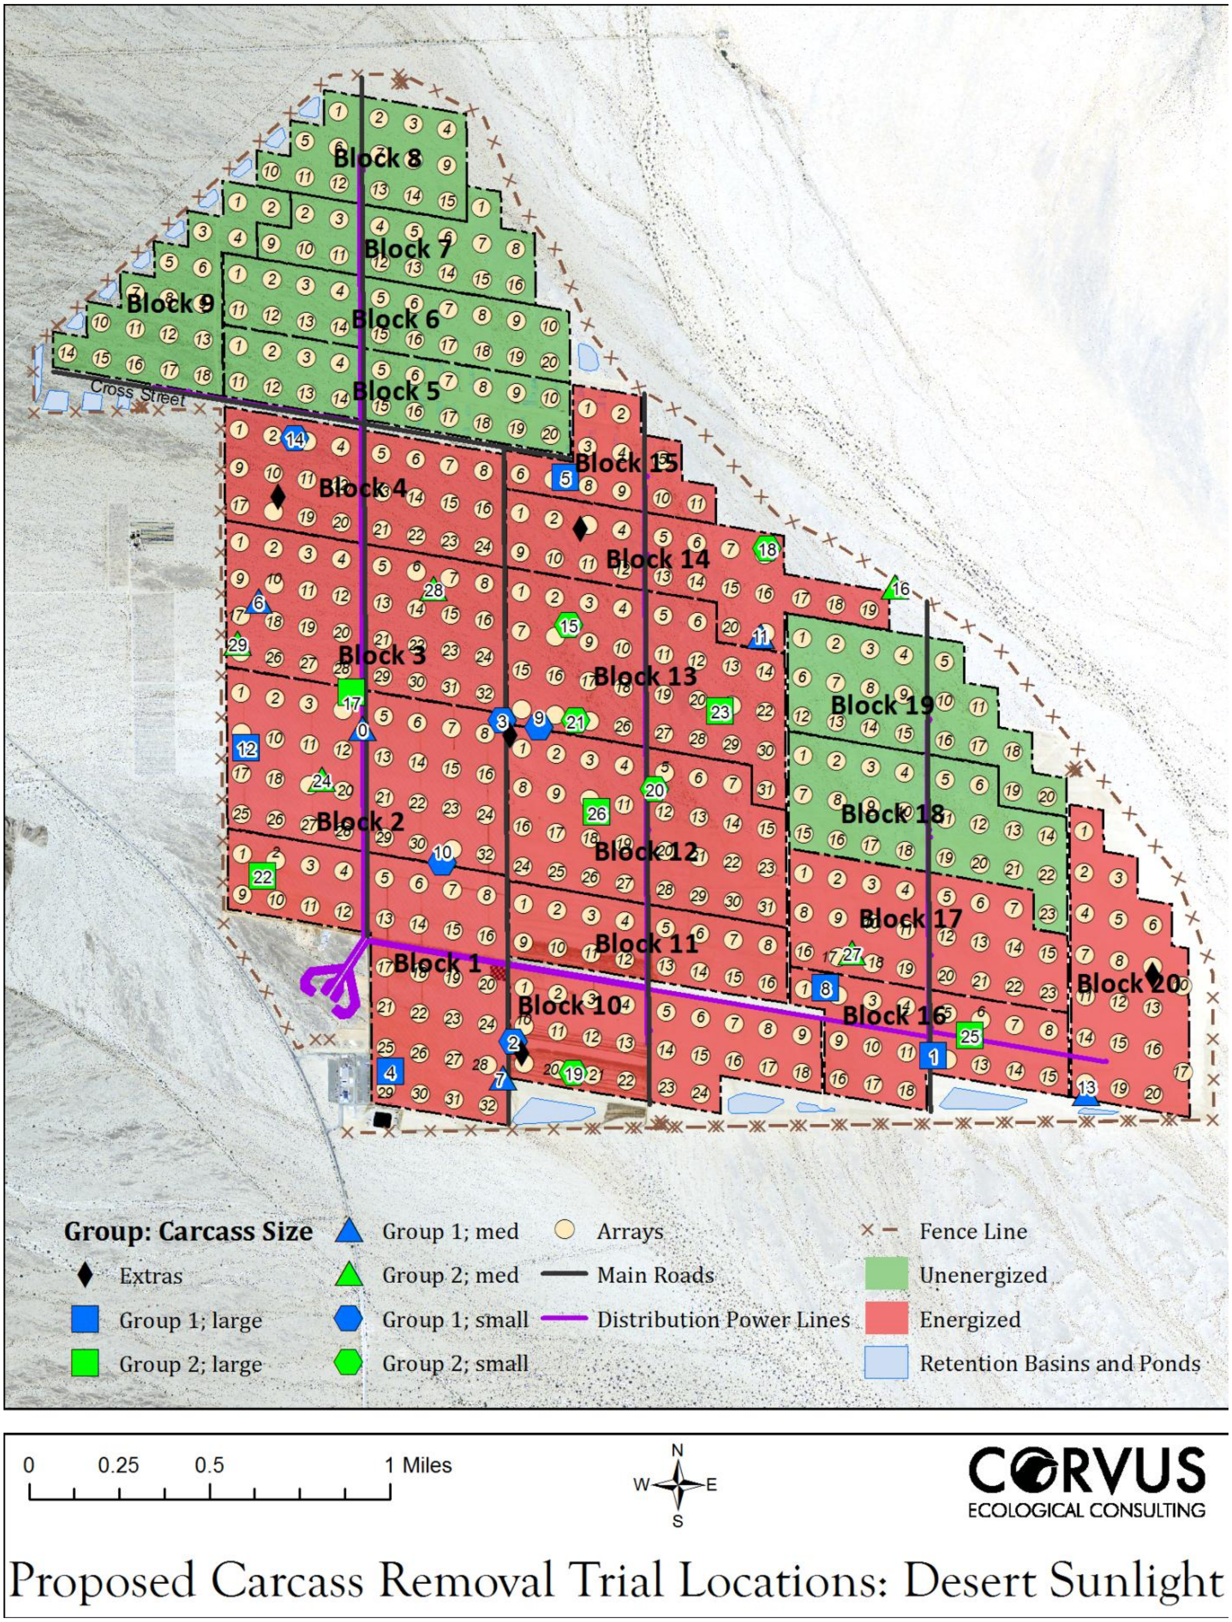

Figure 1 Randomized and Spatially-Balanced Trial Specimen Locations Within the Sample Area.

Timing of Carcass Placements

To minimize potential bias caused by scavenger swamping (Smallwood 2007, Smallwood et al. 2010) trial specimens will be placed over a fifteen-day period. Five days after the installation of thirty game cameras, fifteen trial specimens (five small, five medium and five large) will be placed at random locations within the Study Area. A game camera will be setup within 40-feet of each trial specimen. The initial placement of trial specimens will mark the beginning of the trial period. Fifteen days after the beginning of the trial period, fifteen additional trial specimens (five small, five medium and five large) will be placed at pre-determined random and spatially-balanced locations within the Sample Area. The placement of trial specimens will not be duplicated at any single camera placement and all cameras will remain in place and fully operational throughout the trial period. Trial specimens will be collected (if applicable) thirty days after their placement. The Carcass Removal Assessment will be complete thirty days after the placement of the second group of trial specimens, forty-five days after the beginning of the trial period.

Trial Specimens

Trial specimens will consist of the following size classes/ species:

- Small/ House Sparrow (*Passer domesticus*)
- Medium/ Eurasion Collared-Dove (*Streptopelia decaocto*)
- Large/ Ring-necked Pheasant (*Phasianus colchicus*)

Trial specimens will include only intact, fresh (i.e., estimated to be no more than 1–2 days old and not noticeably desiccated) bird carcasses that were frozen immediately following death.

All carcasses will be handled with latex gloves and handling time will be minimized. All trial specimens will be inconspicuously marked by clipping a toe to distinguish them from unmarked fatalities and other trial specimens.

Periodic Ground-based Monitoring

Biologists will periodically check the placement of each trial specimen to guard against misleading indicators of carcass removal, such as wind blowing the trial specimen out of the camera's field of view. To minimize the potential for scavenger bias caused by the activity pattern of biologists, every camera will be checked (not just those with trial specimens) following a standard schedule. The placement of trial specimens may be checked from a distance, using spotting scopes or binoculars, to avoid close approach. At least once every week, cameras will be checked for proper functioning at the same time that ground-based monitoring is performed.

The following table provides a standard schedule which outlines the periodic ground-based monitoring of trial specimens:

Table 1 Carcass Removal Assessment – Standard Schedule

TRIAL PERIOD - DAYS	TRIAL SPECIMEN GROUP 1 DISPOSITION	TRIAL SPECIMEN GROUP 2 DISPOSITION	GROUND-BASED MONITORING	CAMERA DISPOSITION/ CHECK

21	X	X	X	X
30	REMOVE	X	X	X
37	NONE	X	X	X
45	NONE	REMOVE	X	REMOVE

SUMMARY

Carcass removal assessment are a critical component to the overall sampling design aimed at calculating fatality estimates. The fatality estimate will be adjusted for variation in carcass persistence by applying seasonal correlation factors to data for each carcass size class. These data will also be used to inform the search interval for avian carcass surveys.

Ivanpah
2 Year DRAFT Analysis
TAC Presentation

04/19/16

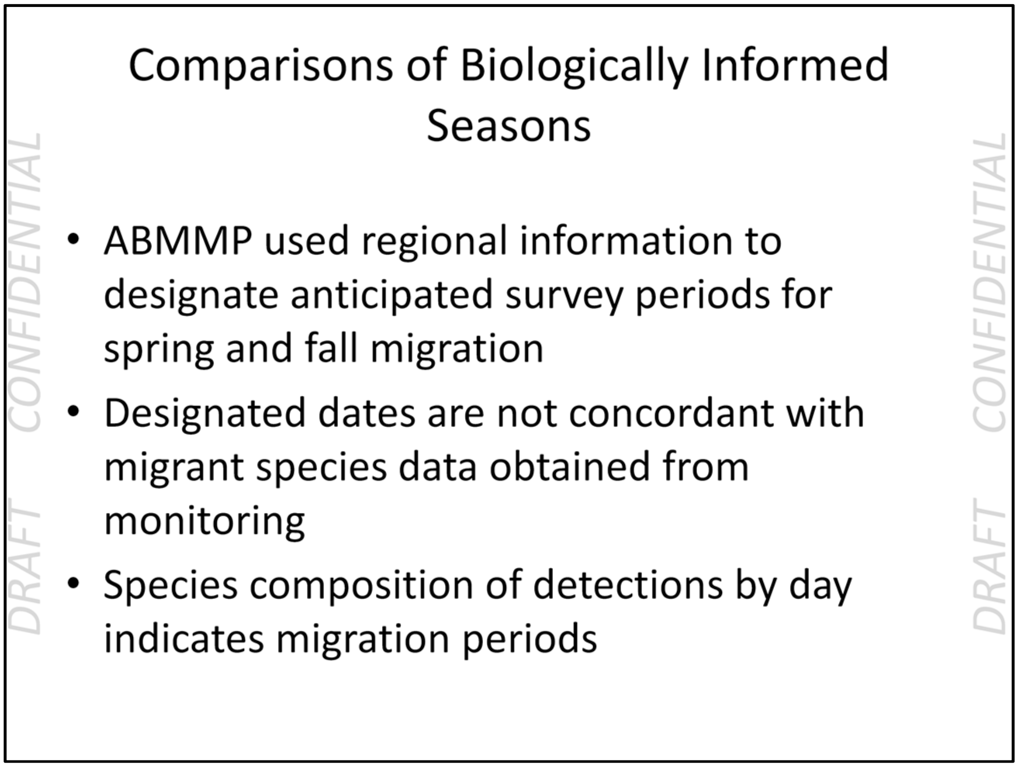
2 Year Draft Analysis

Objective: Obtain meaningful seasonal comparisons

Step 1. Evaluate bird migratory seasons at Ivanpah

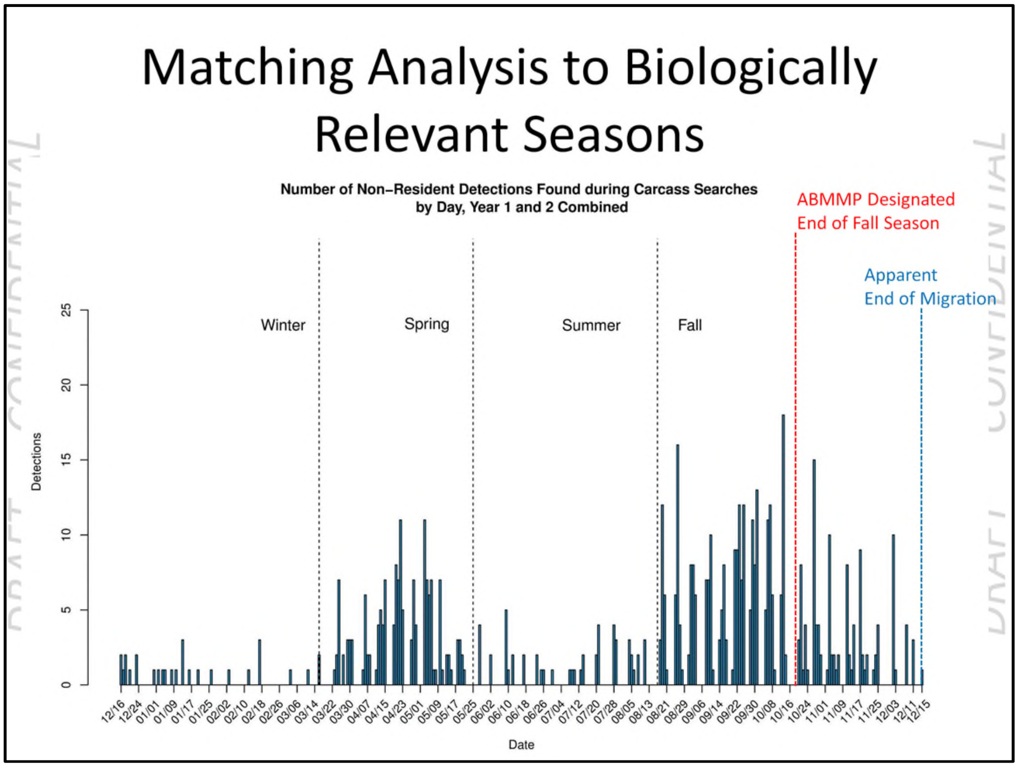
Step 2. Structure seasons to match migratory periods

Step 3. Calculate seasonally adjusted fatality estimates



Comparisons of Biologically Informed Seasons

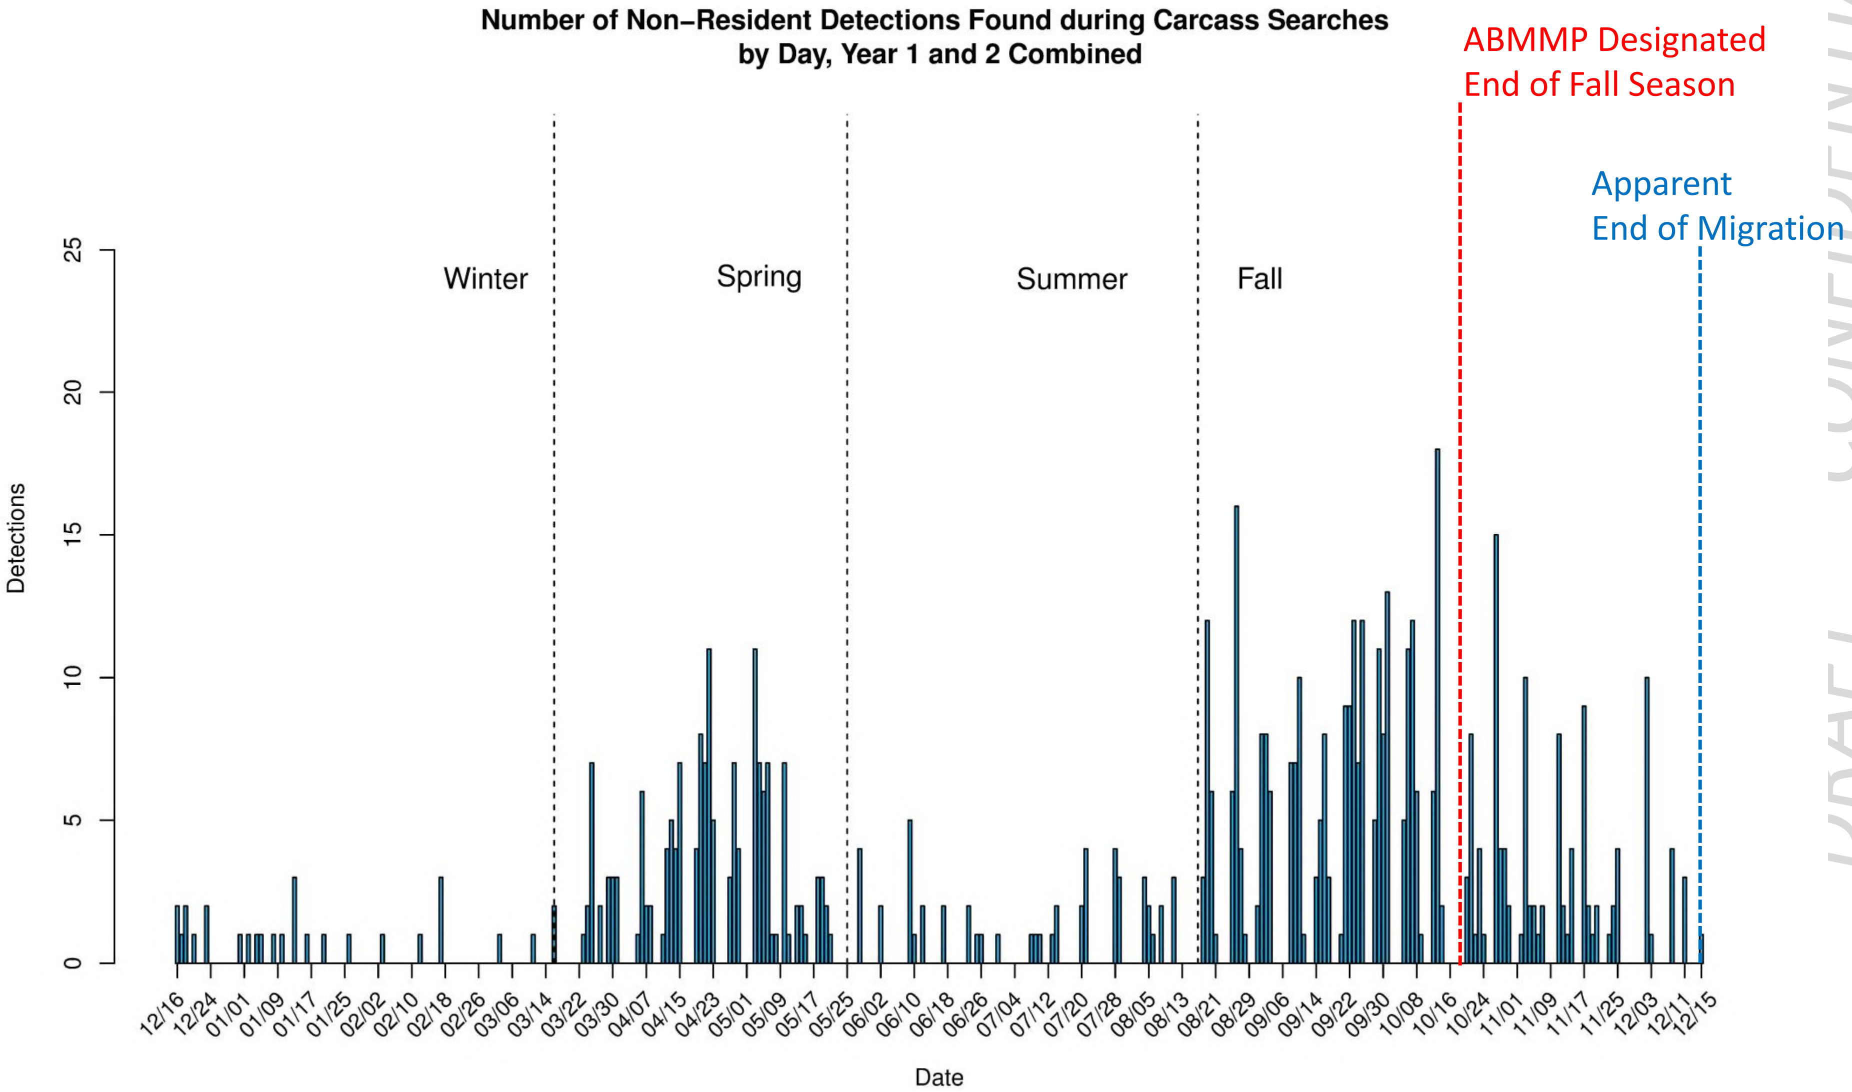
- ABMMP used regional information to designate anticipated survey periods for spring and fall migration
- Designated dates are not concordant with migrant species data obtained from monitoring
- Species composition of detections by day indicates migration periods



Matching Analysis to Biologically Relevant Seasons

-every bird species observed on site was classified as resident or non-resident based on seasonal occurrence site lead biologist
-year 1 and year 2 non-resident detections were aggregated by day
-each bar corresponds to the number of detections found on searches on a particular calendar day, irrespective of year
-red line shows end of "fall" season defined by ABMMP
-blue line shows end of period in which non-resident, migrant birds predominantly show up as detections
-Important note: each survey (or each bar) to the right of the red line corresponds to a search after a 21-day interval. Therefore, each bar represents a "look back" in time; for example
searches on December 03 are capturing fatalities from between November 12 to December 3
-thus, migration likely ends between November 12 and December 3 but based on the survey interval, December 15 is used to define the end of the fall season for analysis
-revised fall seasons dates align with broad patterns in regional migration reported from BirdCast during 2014 and 2015.
-fall migration presents more temporal variation
-survey dates must be comparable between years with season for meaningful comparison regardless of calendar date

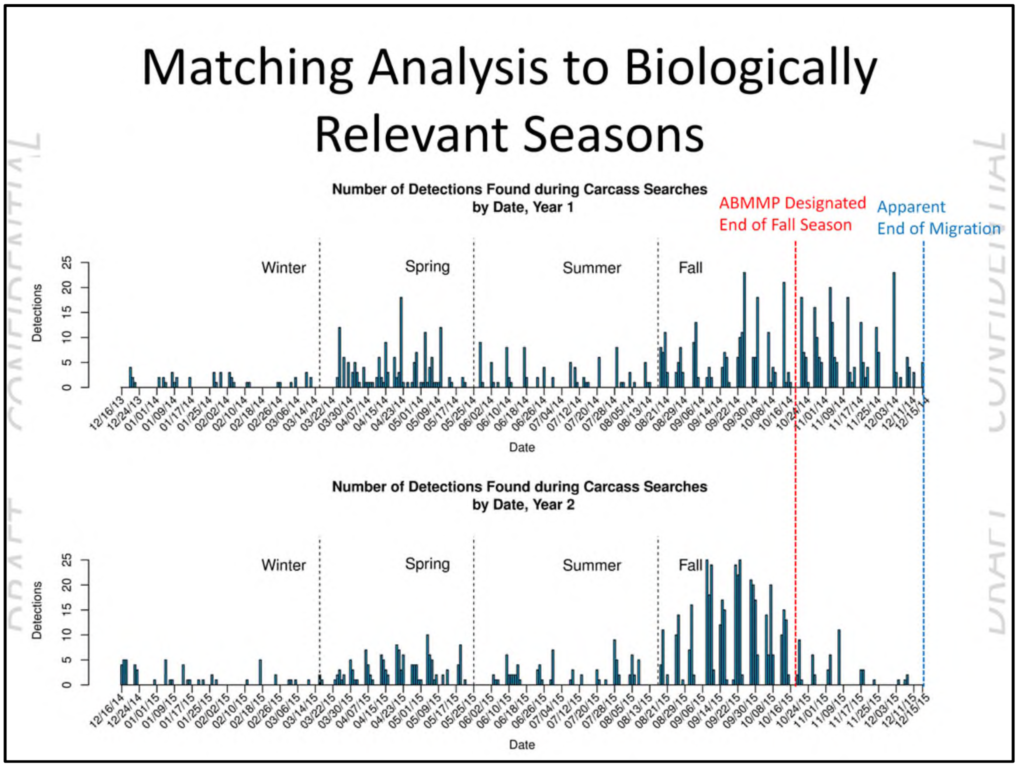
Matching Analysis to Biologically Relevant Seasons



Number of Non–Resident Detections Found during Carcass Searches by Day, Year 1 and 2 Combined

ABMMP Designated End of Fall Season

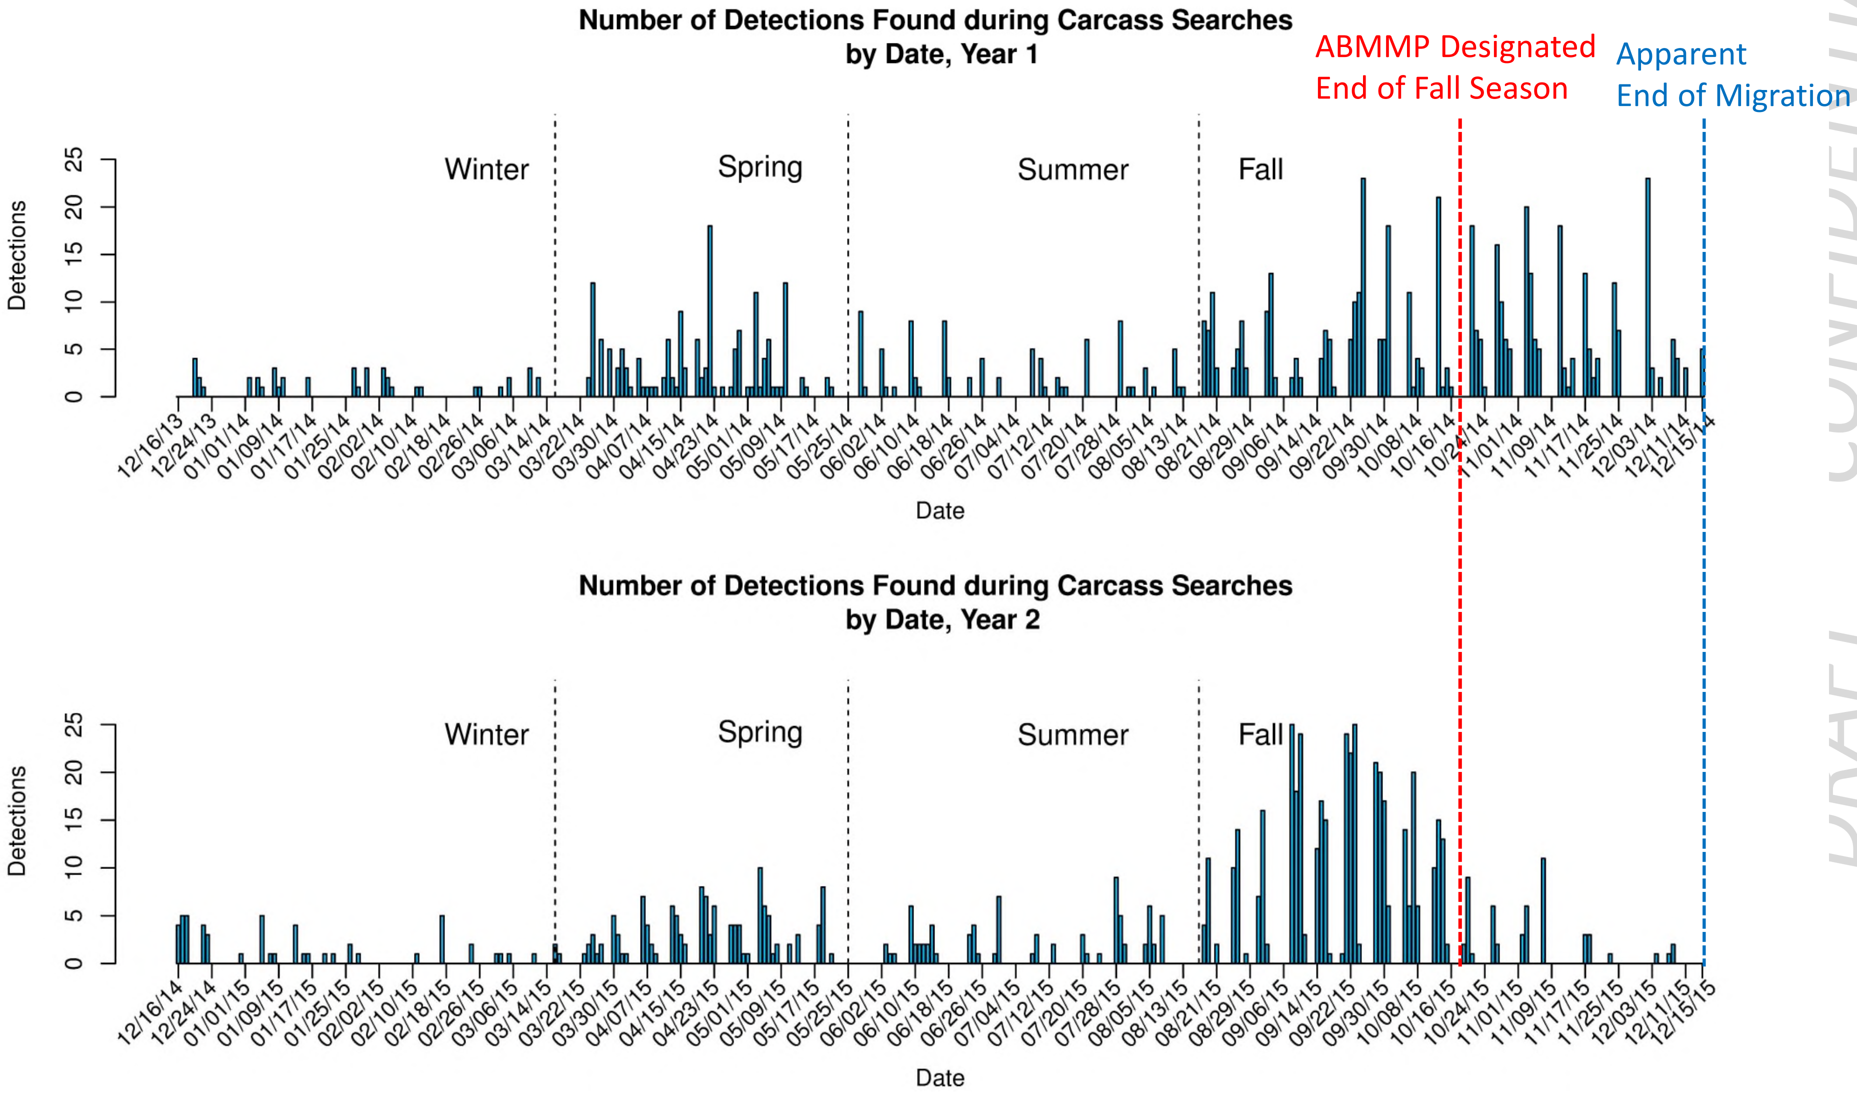
Apparent End of Migration



Matching Analysis to Biologically Relevant Seasons

-number of detections of all species also suggests fall migration extends beyond ABMMP end of fall season
-fall migration shows more temporal variation in migration intensity than spring migration
-although fall migration year 1 longer than year 2, season dates must be aligned for meaningful comparison
-spring migration season and summer season seem well defined by ABMMP season dates

Matching Analysis to Biologically Relevant Seasons

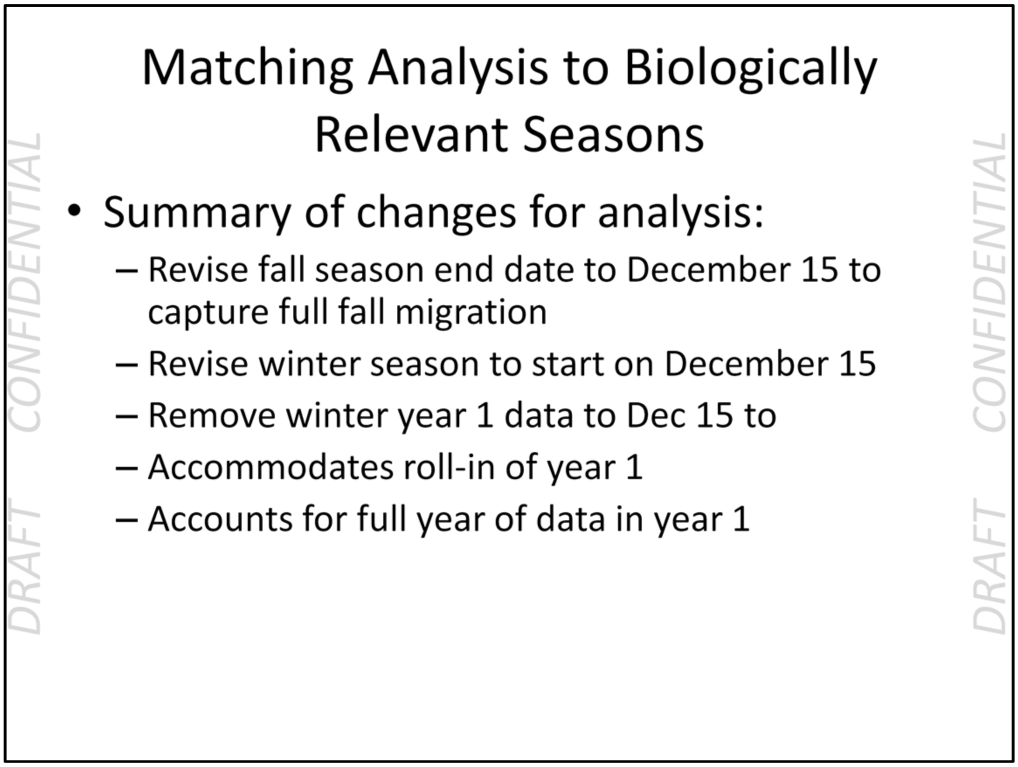


Number of Detections Found during Carcass Searches by Date, Year 1

Number of Detections Found during Carcass Searches by Date, Year 2

ABMMP Designated End of Fall Season

Apparent End of Migration



Matching Analysis to Biologically Relevant Seasons

- Summary of changes for analysis:
  - Revise fall season end date to December 15 to capture full fall migration
  - Revise winter season to start on December 15
  - Remove winter year 1 data to Dec 15 to
  - Accommodates roll-in of year 1
  - Accounts for full year of data in year 1

-change in fall/winter seasons dates allows for more comparable estimates between winter 1 and winter 2. Recall, unit 1 was monitored first in October 2013, followed by unit 3 in early December, and finally unit 2 in early January. Thus, effort and timing of surveys is nearly the same in winter 1 and winter 2 with revised season dates.

Notes on analysis

-The Huso estimator is designed to accommodate variation in search interval during the course of monitoring. The search interval associated with all carcasses found on a given search is calculated, and a survival model is used to estimate the average probability of persistence for each carcass. Therefore, no issues are presented by calculating estimates for a season with a variety of search intervals (i.e. 7-day search intervals in fall up to October 20, followed by 21-day search intervals until December 15).

-Changing the dates for fall/winter seasons does not affect the searcher efficiency or carcass persistence models used to adjust estimates. Biologically informed season dates are utilized to 'bin' fatalities in the most meaningful and consistent way for the purposes of comparing season and years of monitoring at Ivanpah. See below for treatment of searcher efficiency and carcass persistence

> **searcher efficiency**: searcher efficiency data were collected according to the study design and seasons defined in the ABMMP. The top searcher efficiency model has covariates for carcass size and location (2 visibility classes). Since there are no covariates for season or year, searcher efficiency is estimated independent of season dates. The same searcher efficiency model was used to produce annual estimates and seasonally adjusted estimates.

> **carcass persistence**: carcass persistence trial data were collected according to the study

design and seasons defined in the ABMMP. The carcass persistence models were fit for small birds and large birds separately; The top models included a covariate for season for small birds, and an intercept only model for large birds (i.e. no season or location effect). The same carcass persistence models were used to produce annual estimates and seasonally adjusted estimates. The seasons used in the small bird model were defined by the dates described in the ABMMP. Thus, small birds were adjusted for carcass persistence according to the ABMMP season date ranges.

SUMMARY

There are two basic types of solar energy technology: photovoltaic and concentrating solar power. As the number of utility-scale solar energy facilities using these technologies is expected to increase in the United States, so are the potential impacts on wildlife and their habitats. Recent attention is on the risk of fatality to birds. Understanding the current rates of avian mortality and existing monitoring requirements is an important first step in developing science-based mitigation and minimization protocols. The resulting information also allows a comparison of the avian mortality rates of utility-scale solar energy facilities with those from other technologies and sources, as well as the identification of data gaps and research needs.

This report will present and discuss the current state of knowledge regarding avian issues at utility-scale solar energy facilities by:

1. Summarizing available avian fatality data and issues;
2. Summarizing current monitoring activities and reporting requirements;
3. Summarizing avian mortality data for non-solar development activities;
4. Summarizing mitigation measures being used or considered by solar developers;
5. Evaluating mitigation measures that have been successfully employed for non-solar activities for those that may be effective for solar development;
6. Examining solar-technology-specific aspects of avian fatality, including solar flux associated with power towers; and
7. Recommending future steps.

Several federal and state regulations apply to the protection of birds at solar energy developments. Most birds are protected by the Migratory Bird Treaty Act, which prohibits the taking, killing, possession, transportation, and importation of migratory birds, their eggs, parts, and nests, except when authorized by the U.S. Fish and Wildlife Service. Projects are also required to comply with state and federal regulations to protect threatened, endangered, and certain other species (e.g., Endangered Species Act, Bald and Golden Eagle Protection Act, Bureau of Land Management policy, and state wildlife codes). Because the potential for impact to birds and their populations depends largely on project size and location, specific requirements for threatened, endangered, and sensitive bird species are often considered on a project-specific basis.

Like many industrial activities, utility-scale solar energy development has the potential to impact, directly and indirectly, birds and bird communities in a number of ways, such as by habitat degradation, habitat loss, habitat fragmentation, and direct fatality. This report summarizes existing information about direct impacts, of which there are two general types: collision-related and solar-flux-related. Collision-related impacts may occur from all types of solar energy technologies. The effects of solar flux on birds have so far been observed only at facilities employing concentrated-solar-power towers.

Information and data summarized in this report were collected directly from solar energy companies, industry organizations, and state and federal regulatory agencies, as well as through Internet searches. Compared with other industries, there are relatively few reports that describe or quantify the interaction of birds with utility-scale solar power facilities. Most of the available information on solar-avian interactions is from projects in the southwest United States. In total, avian monitoring plans and/or fatality data are known to exist for 15 solar energy facilities (14 of them in the U.S.). Not all utility-scale solar energy developments in the United States are required to prepare project-specific avian monitoring protocols. A Bird and Bat Conservation Strategy (BBCS) may be part of a solar energy application when an environmental review indicates the need for one. The BBCS outlines an approach for assessing the risks for impacts to birds and bats, designing the facility to avoid and minimize risks, and monitoring avian activity and fatalities in the vicinity.

Evaluating avian mortality rates and patterns is important for comparing avian mortality risk for utility-scale solar facilities with that for other energy developments. However, as discussed in this report, data collected to date from utility-scale solar facilities are not adequate to support such evaluations and comparisons. Avian fatality data were available for seven solar energy facilities in the United States. Of these, systematic avian fatality data were available for only four.

Available project-specific data, discussed in this report, are presented in Appendix B. Existing monitoring requirements and mitigation measures employed by the solar industry and other industries are also presented in this report. Specific solar energy technological factors that have been identified and possibly associated with avian fatality, including solar flux, are discussed.

Standardization of data collection and methodology is essential for comparing avian mortality between projects and across industries. However, the paucity of information for solar energy facilities and its lack of standardization make it impossible to develop an industrywide avian mortality estimate or comparison with any scientific certainty. Standardized methods would increase certainty in mortality estimates by accounting for the following factors that may bias mortality calculation: searcher efficiency, search effort, predation and scavenging, and the role of background mortality.

On the basis of the findings presented in this report, several recommendations can be made to improve understanding of avian fatality issues at utility-scale solar energy facilities. There is a basic need to understand the cause of fatalities (e.g., collision, flux, and predation) within solar arrays and associated infrastructure for a variety of avian species. The findings presented in this report point to several recommendations for improving understanding of avian fatality issues at utility-scale solar energy facilities:

1. Not all utility-scale solar energy developments in the United States have been required to prepare and comply with project-specific avian monitoring protocols, particularly projects located on private lands. Available BBCSs revealed opportunities to improve consistency and standardization in avian monitoring and reporting protocols. Building upon lessons learned from the wind energy industry, adopting programmatic guidelines similar to those for wind energy would likely (a) promote standardized monitoring, data collection, and reporting throughout the solar energy industry; (b) promote compliance with relevant wildlife laws and regulations; (c) encourage scientifically rigorous survey, monitoring, assessment, and research designs proportionate to the risk to species of concern; (d) produce potentially comparable data from different geographical regions; and (e) mitigate potential adverse effects on species of concern and their habitats using avoidance, minimization, and habitat compensation strategies.

2. More systematic data from solar energy facilities across geographic regions will clarify avian risks of the solar industry and allow comparison with risks of other energy sources. Standardized monitoring methodologies and assessment approaches will vastly improve the scientific certainty of conclusions about avian risk and mortality; the types of birds impacted; the contribution of background mortality to fatality data sets; the influence of facility attraction to birds; and other factors, such as predation.

3. As efforts get under way to increase the amount and compatibility of avian mortality data collected from utility-scale solar facilities, researchers should seize the opportunity create science plans to tailor data collection to their research needs to inform future decisions about solar energy project siting and design. Such science plans should focus on (1) uncertainties related to avian risks and causative factors; (2) population-level impacts to migratory birds; (3) development of more effective inventory and monitoring techniques; and (4) guiding the development of pilot studies to assess causative factors, the potential to mitigate effects, and the implications of mitigation measures and best management practices to energy production.

Moving forward, the industry, federal and state agencies, and other stakeholders might all benefit from working collaboratively towards (1) developing and implementing useful and scientifically rigorous data collection program, (2) evaluating avian mortality related to utility-scale solar development and the causal effects, and (3) identifying appropriate mitigation measures to address identified issues.

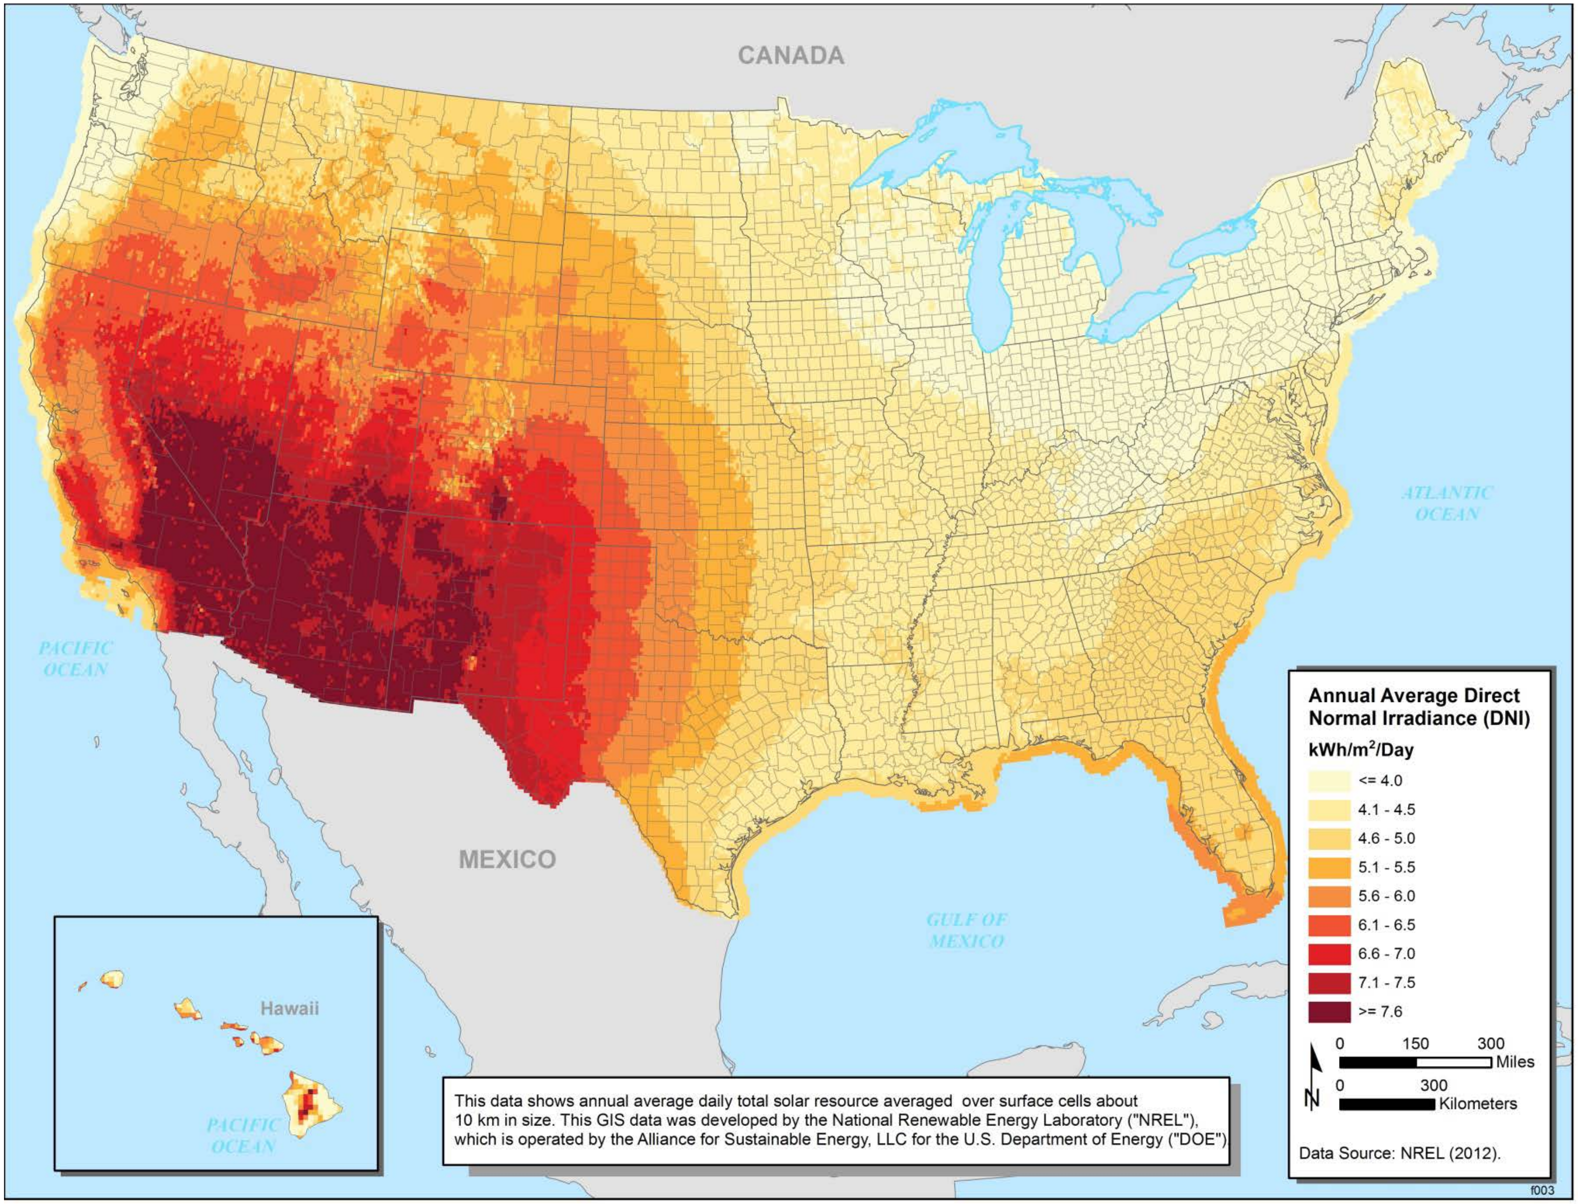
1 INTRODUCTION

Renewable energy development has been increasing as an alternative to fossil-fuel-based technologies, in large part to reduce toxic air emissions and carbon-dioxide-induced effects on climate (Shafiee and Topal 2009; Allison et al. 2014). According to the U.S. Energy Information Association (2014), electric generation from renewables in the United States has increased by more than 50% since 2004, and renewable energy sources currently provide approximately 14% of the nation’s electricity. Solar energy-based technologies represent a rapidly developing renewable energy sector that has seen exponential growth in recent years (Lewis 2007; Bolinger and Weaver 2013). Electrical generation from solar energy is expected to more than double between 2013 and 2015, with about two-thirds of new solar capacity built in California (EIA 2014).

Utility-scale solar energy projects generate electricity for delivery via the electric transmission grid and sale in the utility market. This differs from distributed solar energy systems which are designed at smaller scales (<1 MW). According to the Solar Energy Industries Association (SEIA 2014a), there currently are approximately 800 utility-scale solar energy projects (>1 MW) that are either planned, under construction, or in operations in the United States, representing more than 43 GW of electric capacity. Models developed by the National Renewable Energy Laboratory (NREL 2012) indicate the greatest solar resource potential in the United States is in the Southwest (Figure 1). Indeed, the SEIA (2014b) map in Figure 2 shows that most domestic utility-scale solar development is in Arizona, California, Colorado, Nevada, New Mexico, and Utah.

There are two basic types of solar energy technology: photovoltaic (PV) and concentrating solar power (CSP). Photovoltaic systems use cells to convert sunlight to electric current, whereas CSP systems use reflective surfaces to concentrate sunlight to heat a receiver. The heat is converted to electricity using a thermoelectric power cycle. CSP systems typically include power tower systems with heliostats (angled mirrors) and parabolic trough systems (parabolic mirrors). In the United States, most of the electricity produced by utility-scale solar energy projects through 2014 was generated using PV technologies (SEIA 2014b). An overview of utility-scale solar power systems is provided in Section 1.1.

Despite its benefits of reduced toxic and carbon emissions and renewable generation, utility-scale solar development can impact ecological systems and other environmental resources, including species and their habitats (Lovich and Ennen 2011; Hernandez et al. 2014). Recent studies have demonstrated that utility-scale solar developments represent a source of fatality for wildlife such as birds (e.g., Kagan et al. 2014); however, there are relatively few systematic and empirically based studies that address avian fatality issues at solar facilities (but see McCrary et al. 1986; WEST 2014).



This data shows annual average daily total solar resource averaged over surface cells about 10 km in size. This GIS data was developed by the National Renewable Energy Laboratory ("NREL"), which is operated by the Alliance for Sustainable Energy, LLC for the U.S. Department of Energy ("DOE").

Data Source: NREL (2012).

FIGURE 1 Solar Energy Potential in the United States (Source: NREL 2012)

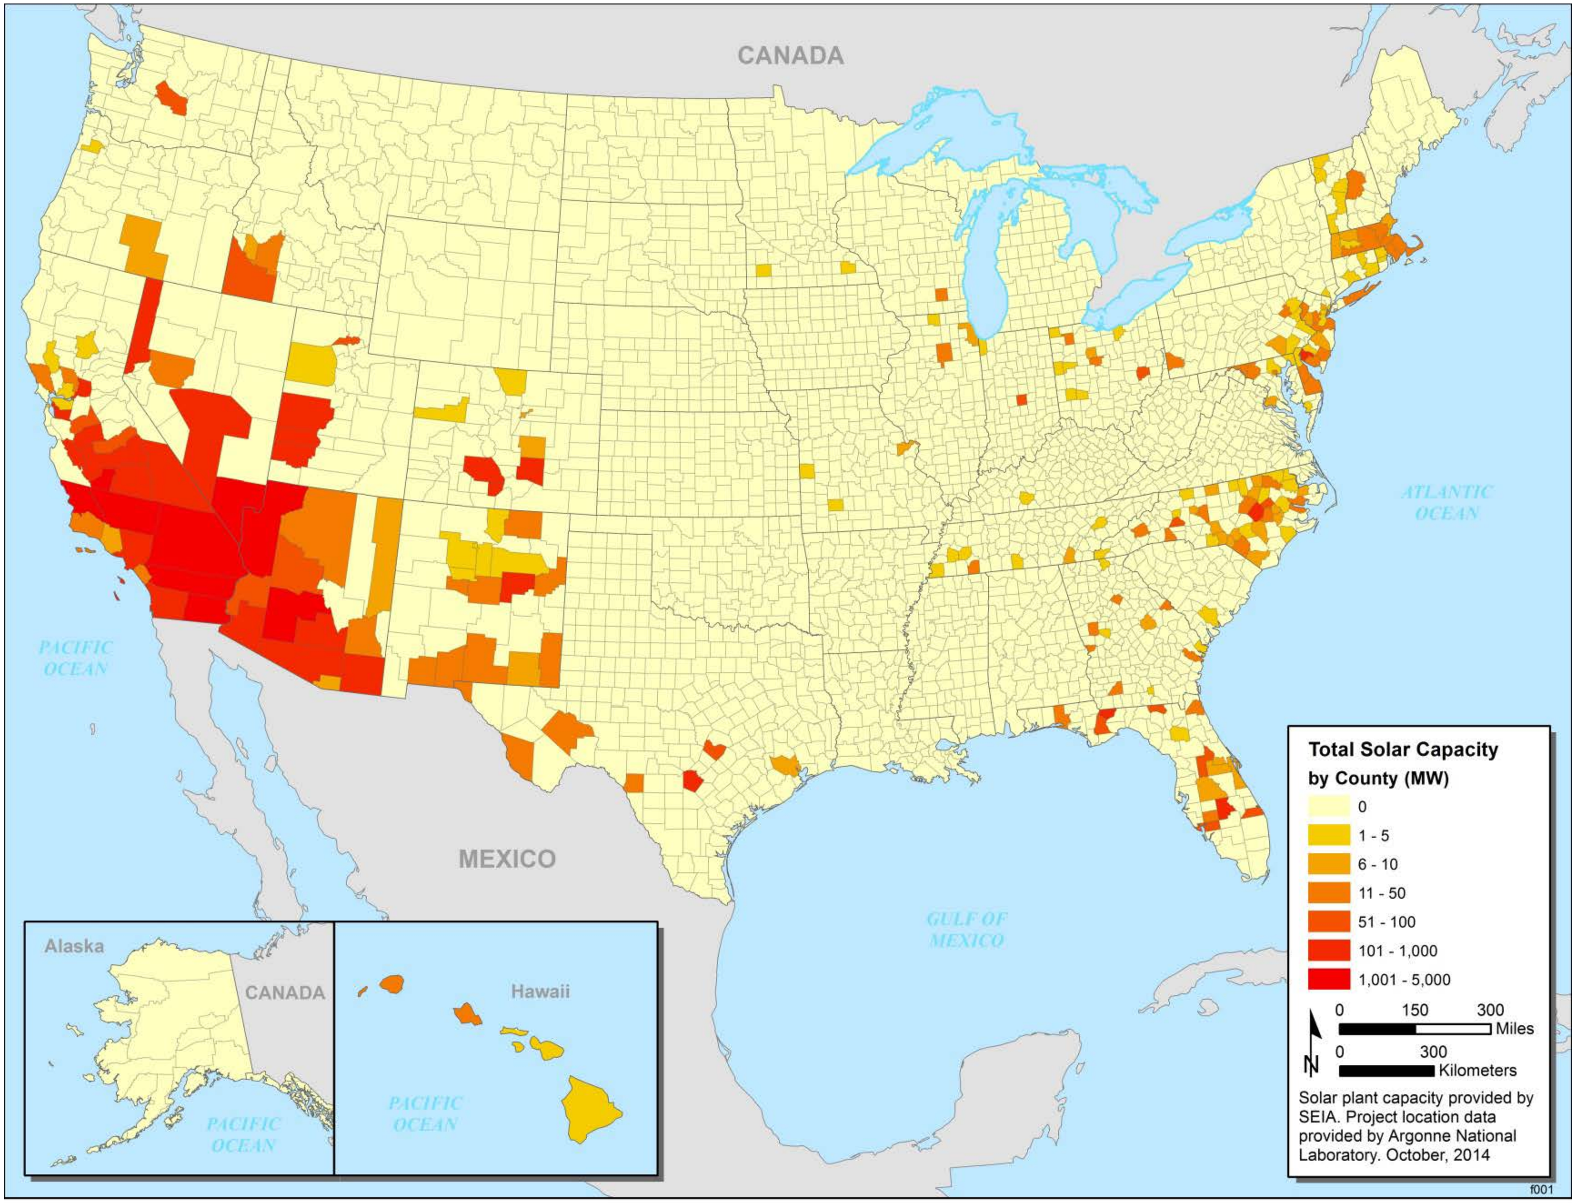


FIGURE 2 Total Solar Utility-Scale Energy Production Capacity (MW) by County (Source: SEIA 2014b)

Understanding current rates of avian mortality at utility-scale solar facilities and existing monitoring requirements is an important first step toward the development of science-based monitoring, avoidance, minimization, and mitigation protocols. Such an effort would aid in understanding the relative mortality rates compared with those from other technologies and sources, as well as the identification of data gaps and potential research needs. The purpose of this report is to summarize the current state of knowledge regarding avian issues at utility-scale solar energy facilities by:

1. Summarizing available avian fatality data and issues;
2. Summarizing current monitoring activities and reporting requirements;
3. Summarizing avian mortality data for non-solar development activities;
4. Summarizing mitigation measures being used or considered by solar developers;
5. Evaluating mitigation measures that have been successfully employed for non-solar activities for those that may be effective for solar development;
6. Examining solar-technology-specific aspects of avian fatality, including solar flux associated with power towers; and
7. Recommending future steps.

1.1 OVERVIEW OF UTILITY-SCALE POWER SYSTEMS

Utility-scale solar power systems are loosely defined as ground-mounted facilities larger than 1 MW_e that are tied directly to the transmission grid. Many facilities are larger than 1 MW_e, and the plants can range up to several hundred megawatts in size and cover hundreds of acres. The growing number of utility-scale solar facilities is a direct result of falling costs of the technologies and the desire to deploy more low-carbon, renewable power into the U.S. electric grid.

Solar power systems are divided into technologies that convert sunlight directly into electricity (PV technologies) and technologies that collect the sun’s light and convert it into thermal energy. PV systems generate power without any appreciable noise, pollution, or fuel consumption; involve few moving parts; and require little routine maintenance, especially when compared with other power-generation technologies. All PV systems consist of three basic subsystems: (1) PV modules; (2) inverters and power electronics; and (3) structural and wiring hardware, commonly referred to as the balance of system. PV modules are fundamentally the same, whether the system is mounted on a residential rooftop or in a large, utility-scale plant.

Solar thermal electric systems, also known as concentrating solar power (CSP) systems, first capture sunlight as heat and then convert the thermal energy into electricity via a thermoelectric power cycle. A CSP plant uses mirrors to focus sunlight onto a “receiver” that contains a flowing liquid, or heat transfer fluid (HTF). The reflectors may be made of glass mirrors or highly reflective polymer films. The hot HTF may be pumped to a storage tank or pumped directly to heat exchangers in the power block to produce steam. Electric power is made by spinning a steam turbine/generator. A major benefit of CSP technologies is the ability to efficiently store the hot HTF and retrieve it later to produce power in periods of poor or no sunlight. The various technologies are summarized in Table 1.

The cost of solar power technologies has fallen dramatically in the past few years due to new technology developments, lower manufacturing costs, and increased deployment volume. Utility-scale plants continue to represent the lowest installed cost and levelized cost of electricity for solar power. PV systems are the most prevalent and lowest-cost solar power technology. CSP systems with thermal energy storage provide more consistent power, with fewer challenges related to grid integration, but they currently have a higher levelized cost per kilowatt-hour.

The most obvious impact of a solar power plant is the occupied land area. Land area per megawatt of capacity depends on several factors, including the solar resource quality, technology, collector/module efficiency, and inclusion of thermal energy storage (for CSP). In general, solar plants occupy between 5 and 10 acres per megawatt of alternating current (MW_{ac}) capacity and between 3 and 4 acres per annual gigawatt-hour of generation (Ong et al. 2013). Including thermal energy storage in CSP plants increases land usage per capacity (acre/MW_{ac}), but decreases land usage per energy generation (acre/GWh). These effects of thermal storage occur because the collector field area increases (to allow charging of storage), and the annual power block operating time increases (when storage is discharged), but the power block size is unchanged. A comparison of land use per gigawatt-hour of generation indicates that utility-scale solar technology has a lower impact than other renewable-generation technologies (such as wind and hydropower) and is comparable to fossil extraction (such as coal extraction) (Fthenakis and Kim 2009).

1.2 REGULATORY CONTEXT

Federal and state regulations provide the legal framework for addressing avian fatality issues at solar energy facilities. Solar projects sited and designed with a federal nexus (i.e., constructed on public land) are required to use the National Environmental Policy Act (NEPA) process and any applicable state environmental planning regulations. Projects without a federal nexus are not subject to NEPA but may be subject to state-level environmental planning regulations. Other federal regulations include the Federal Land Policy and Management Act, Endangered Species Act (ESA), Migratory Bird Treaty Act, Bald and Golden Eagle Protection Act, and policies of federal land managers such as the Bureau of Land Management special status species policy (BLM 2008). State regulations vary by state, but examples include state-level environmental planning requirements (e.g., the California Environmental Quality Act) and policies to protect state-listed special status wildlife (e.g., *California Fish and Game Code*, California Endangered Species Act, and *Nevada State Codes*).

TABLE 1 Common Utility-Scale Solar Technologies

Technology	Key Features	
PV fixed-tilt	• Simplest design, with no moving parts • Thin-film or silicon cells • No cooling water requirement	
PV tracking	• More sun-capturing efficiency because the PV panels rotate to follow the sun • Typically used with crystalline silicon cells • No cooling water requirement	
CSP parabolic trough	• Linear receivers with single-axis tracking • Can include thermal energy storage • Usually wet cooled • Most common and most mature CSP technology	
CSP power tower	• Two-axis tracking heliostats surround a central tower-mounted receiver • Can include thermal energy storage • More cost effective than parabolic troughs • Can be wet or dry cooled	

2 SUMMARY OF AVIAN FATALITY ISSUES AND STUDY METHODOLOGY

2.1 SUMMARY OF ISSUES

One commonality among utility-scale solar facilities of all technology types is that they occupy relatively large spatial footprints to capture the sun's energy. The development of utility-scale solar facilities, therefore, represents a large human land use in the environment, which has the potential to affect birds and bird communities in a number of ways and during all project phases (construction, operations, and decommissioning). The range of potential impacts from utility-scale solar projects on birds and other wildlife has been evaluated in the literature (e.g., Lovich and Ennen 2011; Hernandez et al. 2014) and in the *Final Programmatic Environmental Impact Statement for Solar Energy Development in Six Southwestern States* (BLM and DOE 2012). Like all industrial activities, utility-scale solar energy development has the potential to directly and indirectly impact birds and bird communities in a number of ways (Table 2). In general, direct impacts result from ground-disturbing activities at the project and are observable within the solar project footprint, whereas indirect impacts may extend beyond the solar project footprint as the result of factors such as runoff, water depletion, dust deposition, noise, or visual impacts.

A comprehensive literature review on avian issues at solar energy facilities and other industrial developments was conducted and has been documented in a separate bibliography (Walston et al. 2015). The literature review included peer-reviewed journal articles on avian fatalities from other sources (e.g., wind energy, building collisions), project-specific technical reports on avian monitoring and fatality at solar facilities, information on mitigation measures and best management practices (BMPs), and literature pertaining to avian behavioral patterns and habitat use. In addition to the bibliography, data and information were solicited from U.S. and international solar industry developers and industry organizations.

TABLE 2 Potential Impacts of Utility-Scale Solar Energy Development on Birds and Bird Communities

Direct Impacts	Indirect Impacts
Direct fatality of individual birds	Effects of noise (e.g., behavioral changes)
Direct onsite habitat destruction and/or modification	Road effects
Habitat fragmentation	Effects of altered fire regimes
	Effects of altered surface water and groundwater on habitat condition
	Effects of light pollution
	Effects of spills and pollution
	Effects of electromagnetic fields

Sources: Lovich and Ennen (2011); BLM and DOE (2012).

Although there are several types of direct and indirect impacts (Table 2), this report summarizes existing information of direct avian fatality at utility-scale solar facilities, which represents one of several impact factors. There are currently two known types of direct solar-related bird fatalities (McCrary et al. 1986; Hernandez et al. 2014; Kagan et al. 2014):

1. Collision-related fatality—fatality resulting from the direct contact of the bird with a project structure(s). This type of fatality has been documented at solar projects of all technology types.

2. Solar-flux-related fatality—fatality resulting from the burning/singeing effects of exposure to concentrated sunlight. Passing through the area of solar flux may result in: (a) direct fatality; (b) singeing of flight feathers that cause loss of flight ability, leading to impact with other objects; or (c) impairment of flight capability to reduce the ability to forage or avoid predators, resulting in starvation or predation of the individual (Kagan et al. 2014). Solar-flux-related fatality has been observed only at facilities employing power tower technologies.

The nature and magnitude of impacts on bird populations and communities are generally related to three primary project-specific factors: location, size, and technology (PV vs. CSP) (Lovich and Ennen 2011; BLM and DOE 2012). Bird abundance and activity vary by habitat availability and distribution of other physical features in the environment (e.g., terrain) (Flather and Sauer 1996). Therefore, the location of a solar energy project relative to bird habitats, such as migration flyways, wetlands, and riparian vegetation as well as the preservation or removal of habitat within arrays, could influence the impacts of solar energy development on birds; avoidance or minimization of siting in these sensitive areas can greatly reduce impacts on birds. The size of the solar project (acres) is a direct measure of the amount of surface disturbance and human activity. Thus projects with larger footprints are expected to have greater impacts on birds than projects with smaller footprints. Different solar technologies may vary in the types and magnitude of impacts on birds. For example, it has been hypothesized that projects employing wet cooling technologies would require greater amounts of water than dry cooling technologies, which may increase water demand and alter the availability of surface and groundwater sources to sustain bird habitats such as riparian vegetation (BLM and DOE 2012).

It has been hypothesized that solar-energy-related fatalities for some avian guilds result from bird attraction to the project site (e.g., Kagan et al. 2014). Projects that include evaporative cooling ponds may provide artificial habitat to birds and their prey (e.g., insects). Such projects may attract more birds to the site and result in a greater risk of collision with project structures (Lovich and Ennen 2011; BLM and DOE 2012). Glare and polarized light emitted by solar projects may also attract insects, which, in turn, could attract foraging birds. For example, insects may perceive polarized light as water bodies and may be attracted to such sources (Horváth et al. 2009). Lastly, it has also been hypothesized that utility-scale PV facilities may attract migrating waterfowl and shorebirds through what has been called the “lake effect” (Kagan et al. 2014), whereby migrating birds perceive the reflective surfaces of PV panels as bodies of water and collide with project structures as they attempt to land on the panels. To date, however, no empirical research has been conducted to evaluate the attraction of PV facilities to migrating birds.

The potential impacts of solar energy development on birds can be characterized by evaluating risks to populations and guilds and by understanding mortality risk from solar energy development in the context of mortality risk from other industrial developments. Despite the potential for avian fatality from solar energy development, there is currently little empirical data on avian fatality at solar facilities. Only one systematic study of avian fatality at a utility-scale solar energy facility occurs in the current peer-reviewed scientific literature (McCrary et al. 1986). However, more data have been recently collected at several current solar energy projects and have been synthesized (e.g., H.T. Harvey and Associates 2014a-d; WEST 2014).

Avian fatality at other industrial developments (e.g., energy developments, buildings, and transportation.) has been previously published in the peer-reviewed literature (e.g., Erickson et al. 2005, 2014; Loss et al. 2013; Smallwood 2013; Sovacool 2013). A summary of estimated avian fatalities from anthropogenic sources in the United States is provided in Table 3. To better understand the risk of avian fatality from solar energy development in the context of risks from other sources of fatality, it is important that empirical data be standardized to enable direct comparison among fatality sources. Thus, science-based monitoring designs should be developed to provide systematic collection of fatality data that can be used to calculate overall (e.g., site-wide) mortality estimates that can be compared with other sources of fatality. Systematic monitoring protocols have been identified for a number of solar energy projects through the development of project-specific BBCSs.

Most recent methods to calculate overall mortality estimates (Huso 2011) include factors related to the length of the monitoring period, survey effort, and monitoring frequency, size of the project, searcher efficiency, and the carcass persistence rate. Searcher efficiency is a metric to quantify the ability of searchers to detect carcasses. It typically refers to the percentage of carcasses observed by searchers relative to a known number of carcasses. Based on studies from other industries, factors like bird size and the presence of obstructions, such as vegetation and structures, may influence searcher efficiency (Ponce et al. 2010; Huso 2011). The carcass persistence rate is a metric to quantify the amount of time (usually days) that a carcass is available to be observed before it is scavenged by predators. On the basis of studies from other industries, factors like bird size and densities of predators, such as ravens, may influence carcass persistence estimates (Ponce et al. 2010; Smallwood et al. 2010; Huso 2011).

2.2 TYPES OF INFORMATION AND DATA AND DATA COLLECTED

Currently, there are several sources of information on the potential risks of solar energy development to birds. Project-specific environmental planning documents (e.g., those developed under NEPA or CEQA) describe bird abundance and activity at the project location and evaluate impacts of project development to those bird species and communities. If determined necessary by regulatory agencies, as part of the solar energy applicant’s required measures to reduce impacts, a Bird and Bat Conservation Strategy (BBCS) is prepared that describes in detail the measures to minimize avian fatality at the project. BBCSs are not required for some projects (e.g., those projects located on private lands) and therefore are not known to exist for all utility-scale solar energy projects. BBCSs document the methods to systematically monitor for avian abundance, activity, and fatality at the project location. Implementation of the systematic avian fatality monitoring described within a BBCS for a particular project typically commences following the completion of construction activities. A synthesis of currently available BBCSs for utility-scale solar energy projects is provided in Section 3.3.

There are two types of fatality data collected at a project depending on the nature of the observation—incidental and systematic. Incidental data include fatalities observed incidentally during other activities that were not part of focused systematic searches for carcasses. Systematic data include fatalities observed during the course of dedicated search efforts. The collection and reporting of both types of data may be required for a particular solar project through permits issued by state or federal

TABLE 3 Summary of Annual Avian Fatality Estimates in the United States

Form of Fatality	Erickson et al. 2005	Erickson et al. 2014	WEST 2014	Loss et al. 2013	Sovacool 2013	Smallwood 2013	Loss et al. 2014
Buildings and windows	550 million	—	98 million–980 million	—	97 million	—	365 million–988 million
Power lines	130 million	—	—	—	—	—	—
Cat predation	100 million	—	1.4 billion–3.7 billion	—	110 million	—	—
Vehicles/roads	80 million	—	89 million–340 million	—	—	—	—
Pesticides	67 million	—	—	—	72 million	—	—

agencies, as a condition of the environmental review process, or as established in the BBCS. For example, documentation and reporting of incidental fatality observations at some projects may be required under the federal Migratory Bird Special Purpose Utility permit issued by the U.S. Fish and Wildlife Services (USFWS) (50 CFR Parts 10, 13, and 21.27). There may also be state requirements that govern the reporting of incidental avian fatality data. If available, the project-specific BBCS outlines the methods for collecting and reporting of systematic avian fatality data. In addition, at solar projects that do not have state or federal requirements to monitor and report avian fatalities, these activities may still be conducted on a voluntary basis. Depending on the project and regulatory agencies involved, fatality data may not be made publicly available.

For this report, information on avian monitoring and fatality at solar facilities was obtained using several methods.

1. The major solar energy projects database maintained by the Solar Energy Industries Association (2014b) was used to identify all solar projects in the United States and their attributes (land management, technology, status, etc.).

2. For projects with a federal nexus (e.g., developed on public land), information was requested from federal agencies and obtained from publicly available documents.

3. For projects without a federal nexus (e.g., developed on private land), information was requested from individual developers and/or operators and industry associations such as the Large-Scale Solar Association. Requests for information from industry representatives involved email correspondence and phone conversations.

4. A request for data and information at international solar energy facilities was made by emailing several international solar developers and industry representatives.

5. A comprehensive literature search was performed.

3 SUMMARY AND EVALUATION OF EXISTING AVIAN FATALITY DATA AND ASSOCIATED LIMITATIONS

The literature review reveals a scarcity of published, scientifically vetted information regarding large-scale solar plants and birds. A summary of data and information available at solar facilities, collected as of December 2014 using the methodology described in Section 2, is provided in Table 4. In total, avian monitoring plans and/or fatality data were known to exist for 15 solar energy facilities (14 U.S., 1 international). A summary of those U.S. solar facilities with available fatality data is provided in Table 5. Section 3.1 discusses the limitations of the fatality data, Section 3.2 presents a synthesis of these data, and Section 3.3 summarizes existing monitoring requirements and mitigation measures being employed at solar facilities.

3.1 LIMITATIONS OF AVAILABLE FATALITY DATA

Because avian activity and abundance are known to vary regionally (Somveille et al. 2013; Hurlbert and Haskell 2003; Kuvlesky et al. 2007), standardization of data collection methods and reporting units is essential for making avian mortality comparisons across studies and industries. Many fatality studies are confined to single locations or short time-frames, meaning that variation in weather, bird abundance, and quality of research can result in particularly high or low estimates of fatality leading to inaccurate extrapolations to different temporal periods or geographic scales (Sovacool 2009). In order to understand avian mortality risk at solar facilities in the context of other anthropogenic sources of avian fatality (e.g., Table 3), systematically-based solar-avian mortality estimates need to be calculated to account for potential biases that may occur as a result of survey design and project location. Factors that influence the calculation of avian mortality from survey efforts are summarized in Table 6 and are based upon the work by Huso (2011). These potential bias factors include variation in searcher efficiency, search effort, predation and scavenging, and the role of background mortality in the project’s vicinity. An incomplete understanding of these factors can lead to uncertainty in determining project-specific avian mortality risk. The factors presented in Table 6 represent the common forms of bias in avian mortality estimation and are not intended to reflect a comprehensive list of all factors that influence avian mortality. Mortality risk may also be influenced by the project’s geographic setting in relation to bird migration patterns, seasonal differences in avian activity and abundance, daytime versus nighttime effects, and other factors such as moon phase and weather.

Standardization of data across projects is necessary to systematically calculate an overall solar-avian mortality rate that could be used to understand the overall risk of avian mortality at solar facilities compared with other human installations. However, the available solar-avian fatality data evaluated in this report were too limited and inconsistent to provide an overall avian mortality estimate for the utility-scale solar industry. Of the known solar projects with available avian fatality data presented in Table 5, three projects have publicly available systematic survey results that can be used to estimate annual mortality (Ivanpah Solar Electric Generating System [ISEGS], California Valley Solar Ranch [CVSR], and California Solar One). The three solar facilities with systematic avian fatality data were inconsistent in survey design and methodology, which precluded data compilation to calculate overall avian mortality. Inconsistencies were largely related to (1) certainty in detecting fatalities and relating fatalities to the solar facility, (2) the role of predation and/or scavenging, and (3) the role of background mortality.

Incidental data, while useful in identifying general patterns of fatality, are not appropriate for estimating annual mortality rates due to the potential for biases to be present within incidental observations (e.g., searcher efficiency, scavenger removal; see Table 6). Based upon review of existing information, therefore, it was determined that the available solar-avian fatality data were too sparse and inconsistent to provide a meaningful assessment of overall avian mortality at solar facilities. More systematic study and efforts to standardize data through the development of systematic monitoring protocols are needed to make any conclusions about the avian risks of utility-scale solar development.

3.2 SUMMARY OF AVAILABLE AVIAN FATALITY DATA, MONITORING REQUIREMENTS, AND MITIGATION MEASURES AT EXISTING SOLAR FACILITIES

This section presents a summary of avian fatalities at U.S. solar energy facilities for which incidental or systematic avian fatality data were available. A summary of U.S. solar facilities with available incidental or systematic avian fatality data is provided in Table 5. See Appendix B (Table B.1) for a summary of avian mortality by species among the solar energy facilities reviewed in this report. Over 1,300 incidental and systematic avian fatality observations from seven utility-scale solar projects that were publicly available as of December 2014 were used in this section to evaluate general patterns of avian fatality. All six utility-scale solar facilities are located in the state of California. The data were collected and reported over various monitoring and observation periods from 2011 to 2014. The data used in these evaluations include both incidental and systematic avian mortality data. While only systematic data may be useful in calculating facility-wide avian mortality estimates, evaluations of both incidental and systematic data may reveal general patterns of avian fatality.

General patterns of fatality related to cause of death, taxonomic groups, residency, and status are presented below. Without more complete and systematic data on local avian abundance and activity near solar facilities, background mortality rates, and the role of predation (including scavenging), a more comprehensive scientific examination of these factors cannot be completed.

3.2.1 Cause of Death

The causes of death documented at solar facilities include solar flux, impact trauma, predation trauma, electrocution, and emaciation; however, the cause of death is often unknown (Kagan et al. 2014). With the exception of California Solar One, the cause of death could not be determined for the majority of bird deaths at all solar facilities. Solar flux was the second-ranked cause of death at the two power tower solar facilities (ISEGS and Solar One). Collision ranked second at Desert Sunlight, CVSR, and Genesis. At Topaz, predation ranked second. It is important to note that fatality observations made within these large solar facilities may not be caused by the project facilities. Cause of death could not be determined for over 50% of the fatality observations and many carcasses included in these analyses consisted only of feather spots (feathers concentrated together in a small area) or partial carcasses, thus making determination of cause of death difficult. It is anticipated that some unknown fatalities were caused by predation or some other factor unrelated to the solar project (e.g., H.T. Harvey and Associates 2014a-d; WEST 2014).

TABLE 4 Summary of Available Information on Avian Fatality and Monitoring at Utility-Scale Solar Facilities (January 2015)

Project Name	Location	Technology Type and MW (in Parentheses)	Current Status	Land Type	Available Avian Monitoring Plan	Known Collection of Avian Fatality Data
Mohave Solar	Harper Dry Lake, CA	CSP – Trough (250)	Operational – January 2015	Private	NA[a]	Yes – Incidental[b]
California Solar One	Daggett, CA	CSP – Power Tower (10)	Decommissioned in 1987	Private	NA	Yes – Systematic[c]
California Valley Solar Ranch	San Luis Obispo County, CA	PV (250)	Operational – Oct 2013	Private	Yes[d]	Yes – Systematic[e,f]
Campo Verde	Imperial County, CA	PV (139)	Operational – Oct 2013	Private	NA	Yes – Incidental[b]
Centinela Solar Energy	Imperial County, CA	PV (170)	Operational – August 2013	Private	Yes[g]	NA
Crescent Dunes	Nye County, NV	CSP – Power Tower (110)	Construction completed	Public	Yes[h]	Yes – Systematic[i]
Desert Sunlight	Desert Center, CA	PV (550)	Operating and under construction	Public	Yes[j]	Yes – Incidental[b]
Genesis	Blythe, CA	CSP – Trough (250)	1st Unit Operational – Nov. 2013 2nd Unit Operational – March 2014	Public	Yes[k]	Yes – Incidental[b,l]
Ivanpah Solar Electric Generating System (ISEGS)	San Bernardino County, CA	CSP – Power Tower (377)	Operational – Oct. 2013	Public	Yes[m]	Yes – Incidental[b,l] and systematic[n]
Palen Solar Electric Generating System (PSEGS)	Riverside County, CA	CSP – Power Tower (N/A)	Application submitted	Public	Yes[o]	NA

Project Name	Location	Technology Type and MW (in Parentheses)	Current Status	Land Type	Available Avian Monitoring Plan	Known Collection of Avian Fatality Data
Rice Solar	Riverside County, CA	CSP – Power Tower (150)	Under development	Private	Yes[p]	NA
Silver State North	Primm, NV	PV (50)	Operational – May 2012	Public	Yes[q]	NA
Silver State South	Primm, NV	PV (250)	Under construction	Public	Yes[r]	NA
Topaz Solar Farm	Carrizo Plains, CA	PV (550)	Under construction	Private	Yes[s]	Yes – Systematic[e]
Solar Demonstration Plant	Dimona, Israel	CSP – Power Tower	Operational – 2008	Unknown	NA	Yes[t]

TABLE 6 Factors Influencing Mortality Rate Calculation (Sources: Huso 2011; H.T. Harvey & Associates 2015; Avian & Bat Monitoring and Management Plan for the Ivanpah Solar Electric Generating System)

Factor	Description
Searcher efficiency	The percentage of fatalities found by individual searchers or teams of searchers. Mortality rate estimations are influenced by how well a searcher can detect the actual number of birds within the project. Searcher efficiency percentage is typically determined by conducting field trials, where a predetermined number of bird carcasses of various sizes are placed in the different areas throughout the project footprint and searchers record the number of birds detected. The adjustment for searcher efficiency is a common bias-correction tool employed in mortality estimation for many studies.
Search effort	The percentage of the project footprint surveyed over space and time. Overall mortality estimates are typically calculated for 100% of the project footprint's area. Therefore, surveys of less than 100% of the project often require an adjustment to estimate mortality across the entire footprint. Similarly, overall mortality estimates are calculated for a standard unit of time (e.g., annually). Therefore, surveys of different temporal periods often require adjustment to standardize mortality estimates on an annual basis.
Predation and scavenging	Predators and scavengers may transport carcasses on and off the project footprint, and may therefore contribute to uncertainty in mortality estimation. Carcass removal trials are commonly used to quantify the amount of time (days) that a carcass usually persists in the field before it is removed by predators and scavengers. The adjustment for carcass removal is a common bias-correction tool employed in mortality estimation for many studies. Recent studies have highlighted the potential for predators to transport carcasses to the project footprint from offsite locations, where the bird may have died from causes unrelated to the project. Understanding the role of this form of background mortality in the estimation of solar-avian mortality has been identified as a need for future research.
Background mortality	An estimate of natural avian mortality occurring independently from human-caused fatality. Some avian fatality observations within project footprints may be attributable to background mortality. To better understand background mortality and adjust project-related mortality estimates, background mortality is examined by surveying for avian fatality in offsite reference areas (i.e., control plots). Background mortality studies at utility-scale solar facilities have shown that a large portion of fatalities may be attributable to background and unrelated to the project. Mortality estimates at some solar facilities have been calculated with adjustments to account for background mortality.

3.2.2 Species Composition

The species composition of reported avian fatalities at the seven utility-scale solar facilities is summarized in Appendix B (Table B.1). Passerines were the taxonomic group most frequently found killed or injured at all six California solar energy facilities, ranging from 39.6% to 62.5% of the avian mortalities. Doves and pigeons had the next highest overall percentage; however, the order of rankings varied among facilities.

Water-dependent species (loons, grebes, rails, coots, shorebirds, waterbirds, and waterfowl) have been considered vulnerable to fatality at PV facilities because of the potential for them to confuse arrays for bodies of water (the lake effect hypothesis) (Kagan et al. 2014; WEST 2014). Based on the limited number of solar projects reviewed, observations of fatality by taxonomic groups were too inconsistent to test the lake-effect hypothesis. Overall, water-dependent species represented 11.2% of all fatalities, but there was high variability among solar facilities, ranging from 0.27% at CVSR to 45.5% at Desert Sunlight. At all three PV facilities (Topaz, Desert Sunlight, and CVSR), water-dependent species accounted for an average of 12.9% of fatalities, while at all three CSP facilities (ISEGS, Solar One, and Genesis) water-dependent species accounted for an average of 11.2% of mortalities. Water-dependent birds represented the greatest proportion of mortalities at only one facility (Desert Sunlight).

Although these preliminary fatality observations do not show a clear association between waterbird fatalities and the lake-effect hypothesis, the sample size (e.g., number of solar facilities) was too limited to allow for statistical analysis of this hypothesis. It is therefore too speculative using the existing data to make any conclusions about the influence of the lake effect or other factors that contribute to fatality of water-dependent birds. The activity and abundance of water-dependent species near solar facilities may depend on other site-specific or regional factors (such as the surrounding landscape) that have not yet been investigated (WEST 2014). It is important to note that not all fatality observations of water-dependent birds within the project footprint may have been caused by the project facility. Cause of death could not be determined for the majority of the fatality observations (Section 3.2.1).

A total of 20 birds (about 1.5%) found dead or injured at all six California solar energy facilities belonged to sensitive species (federally listed, state-listed, or BLM-sensitive). Two, Yuma clapper rail and yellow-billed cuckoo[1], were federally listed or candidates for listing under the ESA (and state-listed in California). Three fatalities of the California state-listed bank swallow, also considered a sensitive species by the U.S. Bureau of Land Management (BLM), also were detected. The remaining 15 avian fatalities were of BLM-sensitive species (brown pelican and burrowing owl). It is important to note that not all fatality observations of sensitive species were necessarily caused by the project facility. Cause of death could not be determined for the majority of the fatality observations (Section 3.2.1).

3.2.3 Residency

Avian mortalities were divided into two residency groups: resident (breeding, winter, or year-round resident) and migrant (passage migrant) (Appendix B, Table B.1). Residency was determined for each identified species based on NatureServe (2014) and the California Department of Fish and Wildlife (2014). The majority of avian fatalities at all facilities were of resident species. The percentage of fatalities that were residents ranged from 63.4% at Genesis to 93.5% at CVSR. The presence of migrants in the vicinity of solar facilities varies seasonally and may lead to seasonal variation of avian mortalities.

---

[1] At the time the fatality observation was made, the yellow-billed cuckoo was a candidate species for listing under the ESA. It is now federally listed as a threatened species under the ESA.

This trend was observed at ISEGS, where transient species accounted for a larger proportion of avian mortalities during the spring than at other times of the year.

3.3 EXISTING AVIAN MONITORING REQUIREMENTS, MITIGATION MEASURES, AND BEST PRACTICES AT SOLAR FACILITIES

This section presents an overview of existing avian fatality monitoring and reporting requirements, mitigation measures, and related BMPs, as identified in available solar project-specific BBCSs, Avian and Bat Protection Plan (ABPPs), or similar avian monitoring plans (hereafter, all such plans are referred to as "BBCSs"). The purpose of this section is to present the current measures used to minimize avian impacts at utility-scale solar energy facilities. As shown in Table 4, BBCSs were available for 10 solar energy facilities; these plans are summarized in Appendix B (Table B.2).

Most BBCSs required operators to conduct preconstruction surveys to assess baseline avian abundance and activities. Some plans established specific preconstruction monitoring requirements, such as the number of years and seasons of baseline data collection, collection of offsite baseline data, and minimum surveyor requirements. Nearly all plans included discussion of species-specific surveys for rare species and most acknowledged that the project would comply with ESA and state wildlife requirements, which could impose additional monitoring requirements.

BBCSs reported various approaches for evaluating avian risks from solar energy development. One important approach to evaluating project-specific impacts was through Before-After Control-Impact (BACI) studies (Smith 2002). Although few BBCSs reported specific plans for BACI evaluations, the majority of the BBCSs reported the collection of baseline information and complementary post-construction data collection at project and offsite locations that would permit a BACI analysis. In addition, while all BBCSs documented the collection and summation of avian fatality detections, several BBCSs reported on the use of specific statistical models to evaluate risk.

Requirements for specifying measures for avoidance, minimization, and mitigation, and BMPs to reduce avian mortality risks, varied among the BBCSs. These measures were identified based on project technology and location relative to the known presence of sensitive species and known avian abundance and activity patterns in the project area. Most projects generally described avoidance of sensitive bird habitats and nest locations. Several BBCSs included measures to minimize the effects of lighting on birds. Several BBCSs also discussed measures to minimize the risk of collision with transmission lines associated with project development. Solar projects with designs for cooling ponds included measures to reduce attraction of birds to the ponds. For projects where sensitive species may be present (e.g., burrowing owls, golden eagles), species-specific avoidance and minimization measures were identified.

4 EXAMPLES OF BEST MANAGEMENT AND OTHER PRACTICES FROM NON-SOLAR INDUSTRIES

This section presents examples of guidance, BMPs, and mitigation measures used for wind energy, power lines, and airports. The focus of this section is on actions used in non-solar industries to reduce avian fatalities, and how these actions might be applicable at solar facilities.

4.1 GUIDANCE, BEST MANAGEMENT PRACTICES, AND MITIGATION MEASURES FROM A SAMPLE OF NON-SOLAR APPLICATIONS

4.1.1 Wind Energy

Wind energy has been deployed in the United States for nearly four decades. Many lessons have been learned since the first wind farm came on line in 1978 in the Altamont Pass Wind Resource Area in California. The specific reasons birds collide with wind turbines remain unclear, but reducing avian collisions with wind turbines is of great importance to nearly all stakeholder groups involved in wind energy development. Proper siting is thought to be a valuable tool for decreasing avian collisions.

Operational minimization (curtailment) and acoustic deterrents have shown promise for reducing bat fatalities at wind facilities. It is unclear whether either of these strategies will be effective in reducing bird fatalities at wind facilities, as rigorous testing has not been conducted. Acoustic deterrents, in general, have not been successful in deterring birds in other applications, primarily due to the short-term nature of their effectiveness, and eventual rehabituation of the species. However, recent research to develop an acoustic deterrent to keep European starlings from foraging has shown promise. Both curtailment and acoustic deterrents may be viable options to reduce avian fatalities at solar facilities; however, research and field testing is needed to determine their efficacies.

To assist the wind energy industry, the USFWS (2012) released *Land-based Wind Energy Guidelines* (WEG), a guidance document for assessing potential adverse effects wind energy might have on species of concern and their habitats. These guidelines are intended to do many things, including promote compliance with relevant wildlife laws and regulations and encourage scientifically rigorous survey, monitoring, assessment, and research designs proportionate to the risk to species of concern. The WEG are intended to produce potentially comparable data across the nation and mitigate potential adverse effects on species of concern and their habitats, using avoidance, minimization, and habitat-compensation strategies. The guidelines are voluntary yet provide BMPs for site development, construction, retrofitting, repowering, and decommissioning.

The tiered approach described in the WEG is an iterative decision-making process for collecting information in increasing detail. The WEG assist wind developers in identifying species of concern that might be affected by their proposed project, including migratory birds, bats, bald and golden eagles and other birds of prey; prairie and sage grouse; and listed, proposed, or candidate endangered and threatened species. Wind energy development in some areas might be disallowed by federal law. Also, other areas may be inappropriate for development because they have been recognized as having high wildlife value based on their ecological rarity and intactness. Details on the five WEG tiers, listed below, can be found within the document. Although WEG guidelines are voluntary, project developers who follow the guidelines and ultimately have unexpected avian impact issues may be better positioned if enforcement actions are proposed by the USFWS.

The five WEG tiers are:

- Tier 1—Preliminary site evaluation (landscape-scale screening of possible project sites)
- Tier 2—Site characterization (broad characterization of one or more potential project sites)
- Tier 3—Field studies to document site wildlife and habitat , and to predict project impacts
- Tier 4—Post-construction studies to estimate impacts
- Tier 5—Other post-construction studies and research

In addition to its Land-based Wind Energy Guidelines, in 2013 the USFWS released the Eagle Conservation Plan Guidance (ECPG) (USFWS 2013). The ECPG provides specific, in-depth direction for conserving bald and golden eagles in the course of siting, constructing, and operating wind energy facilities. Eagles are federally protected by the Migratory Bird Treaty Act and the Bald and Golden Eagle Protection Act (BGEPA).

The ECPG also calls for wind project developers to take a tiered (staged) approach to siting new projects, but is intended for use when applying for an incidental take permit under the BGEPA. The ECPG calls for preliminary landscape-level assessments to consider potential wildlife interactions, then to conduct site-specific surveys and risk assessments prior to construction. It also calls for monitoring all project operations and reporting eagle fatalities to the USFWS, state, and tribal wildlife agencies. Details on each of the stages can be found in the ECPG.

Both the WEG and ECPG took years to develop and adopt. Guidance documents comparable to these may be useful tools for solar project development, although at this time it is not clear that eagles are at risk from such facilities.

BMPs for renewable energy projects in the intermountain west by Jones (2012) were developed primarily for use by conservation organizations. These BMPs are intended to provide guidance to minimize impacts on species and habitats from wind and solar project development in the western United States and are fundamentally based on the best available science. The peer-reviewed Jones report gives special attention to western species and habitats, and its guidance focuses on siting, pre- and post-construction, and operational activities. The document points out that BMPs are not intended to be universally applied, but rather, site-specific assessments need to be conducted.

A number of states have adopted guidelines for wind energy development. While the process for developing state-level guidelines vary, they have many similarities: They are voluntary; they primarily focus on addressing adverse impacts on birds and bats; their objective is to provide a standardized framework for conducting assessments before, during, and after construction; and their results are intended to assess impacts on a broader spatial scale (since virtually all assessments are conducted at a project-specific level). Table 7 summarizes nine state guidelines.

TABLE 7 Summary Wind Energy Guidelines for Nine States

State	Preliminary Site Screening	Pre-Construction Survey Protocols	Impact Assessment and Mitigation	Post-Construction Monitoring and Reporting	Research	Principles for Habitat Mitigation	Reference
Arizona	Yes	Yes	Yes	Yes			AGFD 2009
California	Yes	Yes	Yes	Yes		Yes	CEC and CDFG 2007; Renewable Energy Action Team 2010
Minnesota		Yes		Yes			Mixon et al. 2014
Nebraska		Yes	Yes	Yes	Yes	Yes	NWWWG 2013
New York	Yes	Yes		Yes			NYSDEC 2009
Ohio	Yes	Yes	Yes	Yes			ODNR 2009; Norris 2012
Oregon	Yes	Yes	Yes	Yes		Yes	ODOE 2008
Pennsylvania		Yes		Yes		Yes	PGC 2013
Washington	Yes	Yes	Yes	Yes	Yes	Yes	WDFW 2009

Of the top 10 states expected to significantly contribute to DOE’s 20% wind energy by 2030 scenario (DOE 2008), only California and Minnesota have guidelines in place. Other top states, including Illinois, Iowa, Michigan, New Jersey, North Carolina, Oklahoma, Texas, and Wyoming, do not currently have such guidance. As the United States moves toward the 2030 scenario, it is a reasonable expectation that other states will adopt their own guidelines to address issues for both federal- and state-listed species.

4.1.2 Power Lines

The Avian Power Line Interaction Committee (APLIC) is an organization in the United States that serves as a focal point for avian interaction issues as they pertain to utilities. Formed in 1989 to address whooping crane collisions with power lines, the APLIC originally consisted of 10 utilities, Edison Electric Institute, the USFWS, and the National Audubon Society. Today, APLIC membership includes more than 50 utilities, Edison Electric Institute, the USFWS, Electric Power Research Institute, National Rural Electrical Cooperative Association, and Rural Utilities Service. Further, APLIC’s mission was expanded to address electrocution and collision fatality for many other avian species, especially raptors (APLIC 2014).

The APLIC released *Avian Protection Plan (APP) Guidelines* (2005) and *Suggested Practices for Avian Protection on Power Lines: The State of the Art in 2006* (2006). Both of these documents are considered BMPs for reducing avian collisions and electrocutions with power lines. Like the USFWS’s Land-based Wind Energy Guidelines and Eagle Conservation Plan Guidance, the APLIC’s documents are voluntary and are intended to be used together. The Suggested Practices for Avian Protection on Power Lines is a multifaceted tool with aspects of problem definition; regulation and compliance; biological aspects of avian electrocution; power line design and avian safety; perching, roosting, and nesting issues; and development of an APP. The APLIC’s guidelines can serve as a valuable knowledge base to avoid, minimize, and mitigate adverse avian impacts at utility-scale solar projects.

Details of the various facets within the Practices can be found by reviewing the documents. However, components of an APP are worth mentioning here. An APP outlines a suite of principles designed to reduce avian interactions with electric utility facilities. Although each utility’s APP is different, the overall goal of any APP should be to reduce avian fatality. An APP may contain the following components: corporate policy; training; permit compliance; construction design standards; nest management; avian reporting system; risk assessment methodology; fatality reduction measures; avian enhancement options; quality control; public awareness; and key resources.

4.1.3 Airports

For the period 1990 to 2011, more than 115,000 wildlife strikes were reported to the Federal Aviation Administration (FAA). About 97% of all wildlife strikes reported to the FAA involved birds, about 2% involved terrestrial mammals, and less than 1% involved flying mammals (bats) and reptiles. Waterfowl (ducks and geese), gulls, and raptors (mainly hawks and vultures) are the bird species that cause the most damage to civil aircraft in the United States, while European starlings are responsible for the greatest loss of human life. Vultures and waterfowl cause the most losses to U.S. military aircraft (FAA 2014). Each year in the United States, wildlife strikes to civil aircraft cause about $718 million in damage to aircraft and about 567,000 hours of civil aircraft down time (FAA 2014). Globally, it is estimated that bird strikes cause annual economic impacts of $1.2 billion to commercial aircraft (Allan and Alex 2001; Ning and Chen 2014).

The FAA sponsored the development of a document that "reviews techniques for reducing bird collisions with aircraft and their relative effectiveness" (ACRP 2011). In addition, the FAA has web-based information on its R&D programs and a co-agency publication with the U.S. Department of Agriculture, *Wildlife Hazard Management at Airports: A Manual for Airport Personnel* (Cleary and Dolbeer 2005). The manual is a nearly 400-page document addressing everything from information in the FAA's bird strike database to how to implement and evaluate wildlife hazard mitigation programs.

The International Bird Strike Committee (IBSC 2007) is a voluntary association of "representatives from organizations whose mission is to improve commercial, military, and private aviation flight safety, by sharing knowledge and understanding concerning the reduction of the frequency and risk of collisions between aircraft, birds and other wildlife management practices." The IBSC's BMPs guide airports in wildlife hazard management, active wildlife control, organization and equipment for wildlife management activities, logging of wildlife management activities, wildlife strike reporting, and risk assessment.

The goal of the FAA's R&D program is to mitigate wildlife strikes with aircraft by providing practical resolutions in addition to timely, critical information for pilots and airport managers.
FAA research efforts are focused on four areas: (1) habitat management, (2) wildlife detection methods, (3) wildlife control techniques, and (4) systems integration. Some of these strategies may be applicable to addressing adverse bird impacts at utility-scale solar facilities.

4.2 AVIAN AND BAT PROTECTION PLANS IMPLEMENTED AT WIND FACILITIES

In addition to voluntary federal and state guidelines for reducing bird fatalities at wind facilities, the wind industry is beginning to implement ABPPs (now referred to as BBCSs) at both the company and project levels.

The origination of ABPPs within the wind industry is fairly recent, with the first company-wide ABPP being released by Iberdrola Renewables, Inc. (IR) in October 2008 (IR 2008). This ABPP pre-dates the WEG and is modeled after the APLIC APP, but is expanded to include bats and tailored to meet the needs of wind facilities. IR developed its voluntary ABPP in consultation with the USFWS and includes a corporate policy stating that the wind industry, as it deploys more turbines and project infrastructure across the U.S. landscape, must consider how best to develop projects in a manner to avoid, minimize, and mitigate for adverse impacts on birds and bats in order to ensure a sustainable industry. IR’s ABPP commits at the corporate level to:

- Implement and comply with its own comprehensive ABPP;
- Ensure its actions comply with all applicable state and federal laws, regulations, permits, and ABPP procedures;
- Follow procedures described in the ABPP during the development of all new wind projects in order to understand avian and bat risk at each site and to incorporate features to avoid or minimize impacts on these species;
- For development or operational projects acquired from third parties in merger or acquisition transactions, ensure through the due diligence and acquisition process that preproject or operational practices employed by third parties prior to IR ownership are consistent with the ABPP, or, if not consistent, document inconsistencies, develop a strategy for implementing ABPP practices, and implement ABPP practices as soon as practical;
- Document bird and bat mortalities and injuries at projects and/or structures in order to implement adaptive management actions as necessary;
- Provide information, training, and resources to improve staff knowledge and awareness of the requirements of the ABPP in order to support the ABPP’s successful implementation at both the company level and as applied at specific projects;
- Participate with public and private organizations in programs and scientific research to identify causes and effective controls of detrimental effects of bird and bat interactions with wind projects; and
- Continue to enhance the ABPP by applying lessons learned, research results, new technologies, and latest regulations and guidelines (IR 2008).

While IR is a model for company-level ABPP, incorporation of ABPP at the project level is becoming a more common practice for wind project developers. Project-specific ABPPs follow a common approach but are individualized for the species under consideration and the project location. Many ABPPs are aligned with the USFWS’s WEG, state-specific wind project guidelines, or other similar documents. ABPPs are also being implemented by the solar industry at the project level (see Appendix B for examples).

4.3 TECHNOLOGY SOLUTIONS THAT SHOW PROMISE AS DETERRENTS

Most technology solutions being investigated to reduce wildlife conflicts with wind energy facilities are classified as deterrents. Wildlife deterrents are broadly defined as management techniques that use aversive stimuli to prevent animals from utilizing human resources (Ramp et al. 2011; Schakner and Blumstein 2013). A deterrent stimulus is an aversive, harmful, fearful, or noxious stimulus that elicits a defensive response in a particular animal. This stimulus must create enough real or perceived risk such that the costs of using a resource outweigh foraging or use benefits (Götz and Janik 2011). There are four general classes of deterrents—acoustic, tactile, visual, and chemosensory (Schakner and Blumstein 2013). The following discussion describes each of these modalities and includes information on successes and failures.

4.3.1 Acoustic Deterrents

Acoustic deterrents work by producing a sound painful or distracting enough that it creates aversion and either makes an animal flee or prevents it from visiting an area all together. Acoustic deterrent devices are one of the most widespread nonlethal deterrent methods used, particularly in mammal/fishery conflicts (Fjalling et al. 2006; Schakner and Blumstein 2013). However, their effectiveness in reducing wildlife conflicts at wind energy facilities remains uncertain. In terms of avian collisions with wind turbines, there have been two main issues with using acoustic deterrents: (1) many bird species habituate to sound, so long-term effectiveness is unlikely, and (2) birds and humans hear within the same range, which means that whatever sound is used to deter birds, humans living nearby would also hear the sound (Dooling 2002). It is possible that acoustic deterrents could reduce collisions of migrating passerines because a flock of birds moving through a particular area would likely not habituate to a single noise event. Ultrasonic deterrents have been tried on a few avian species, including gulls and feral pigeons, but were unsuccessful (Soldatini et al. 2007; Eiermann and Heynen 2014).

Other research suggests some options may exist to deter specific bird species. Research on the use of an on-demand cannon system showed promise of deterring waterfowl from landing on oil sands tailing ponds (Ronconi and St. Clair, 2005). Playbacks of calls of various species have shown these methods may also be effective in a continuous playback mode (Ribot et al., 2011; Tupper et al. 2011). The efficacy of a sonic net to deter European starlings from foraging has shown promise (Diekman et al. 2013). Additionally, the use of randomized sounds is being tested, although results are not yet available.

4.3.2 Tactile Deterrents

Tactile deterrents involve physically creating pain or discomfort to induce aversion (Schakner and Blumstein 2013). There is a large body of information on the successes of tactile deterrents for nonflying animals, both marine and land based. However, there is very little information in the peer-reviewed literature on the successes of tactile deterrents with regard to flying animals. Tactile (perch) deterrents on power lines have been tried on raptors with some degree of promise (Slater and Smith 2010). However, some studies were complete failures for various reasons and included photo documentation of raptors actually perched on the perch deterrent (Prather and Messmer 2010). Studies have illustrated that avian perch deterrents are largely ineffective (Duarte et al. 2011), while other types of deterrents, such as electric shock devices, were only somewhat effective at deterring nuisance avian species (Seamans and Blackwell 2014).

4.3.3 Visual Deterrents

Among visual deterrents are novel or intense light, colors, and decoys. In the context of wind energy, a few visual deterrents have been tried or suggested to minimize avian collisions, including ultraviolet-reflective paint (Young et al. 2003), changes in FAA lighting (Gehring et al. 2009), and painting turbine blades different colors (Hodos 2003). Investigations by Hodos (2003) suggested that painting turbine blades combinations of black and white would reduce motion smear of the blades for turbines with high RPMs. Although large commercial-scale turbines have much lower RPMs and motion smear is not an issue, some wind developers in the European Union are in the midst of testing whether painting turbine blades will be effective at reducing avian collisions. To date, there are no published reports of success or failure. A steady-burn lighting regime was shown to reduce bird collisions with structures like meteorological and communication towers (Gehring et al. 2009). At this point, there is little evidence that UV paint and painting turbine blades are effective means for reducing avian collisions. Passerines constitute the largest group of birds at risk of colliding with wind turbines. Most of these collisions occur during their nocturnal migration, so UV paint on turbines would be irrelevant.

4.3.4 Chemosensory Deterrents

Chemosensory deterrents involve aversive scents or things that taste badly. Therefore, animals must have some sort of olfactory capacity for this type of deterrent to work. Although there is a wealth of literature on the use of chemosensory repellents (Kare 1961; Avery et al. 1995; Marples and Roper 1997; Mason et al. 1989; Stevens et al 1998; Engeman et al. 2002), conditioned taste or smell aversion methods to reduce human-wildlife conflicts have produced mixed results in terrestrial ecosystems (Shivik et al. 2003). Additional research is needed to identify chemosensory deterrents that could be effective in reducing avian impacts at solar facilities.

5 TECHNOLOGY-SPECIFIC FACTORS POTENTIALLY ASSOCIATED WITH AVIAN FATALITY

Some facility elements are common to all solar technologies (e.g., structural and wiring hardware, transmission lines, buildings, and roads), but many elements vary by technology. As discussed in Section 2.1, there are two primary types of solar-related avian fatality: collision-related and solar-flux-related fatality. This section discusses specific factors that have been identified as possibly being associated with these two types of fatality. In addition, the results of power tower flux modeling conducted, to provide context for possible ways to mitigate flux-related fatality as part of this study are discussed.

5.1 COLLISION-RELATED FATALITY FACTORS

Collision-related fatality has been observed at solar energy facilities of all technology types. Collisions may occur at any facility (solar or otherwise) with aboveground structures. In the case of solar plants these may include transmission lines, cooling towers, PV panels and poles, trough systems, heliostats, fencing, and buildings. Collisions may also occur at roadways with project vehicles.

At PV and CSP facilities, collision hazards to birds are greatest among the solar field arrays. It has been suggested that PV facilities may attract some species of birds through what has been called the “lake effect” (Kagan et al. 2014), whereby migrating birds perceive the reflective surfaces of PV panels as bodies of water and collide with project structures as they attempt to land on the panels. However, no empirical research has been conducted to confirm or refute this hypothesis.

The primary hazard to birds presented by power-cycle cooling systems is collision with the structures themselves. Cooling structures may also present attractive perching or nesting sites. Wet-cooled systems generally incorporate an evaporation pond to handle water blowdown from the cooling system. Such ponds may be attractive to wildlife, especially in a desert environment.

5.2 SOLAR-FLUX-RELATED FATALITY FACTORS

Based on the study of McCrary et al. (1986) at Solar One, and reported findings of dead birds at the ISEGS power tower facility in California, there appears to be a link between avian fatality and solar flux. Solar flux is a measure of the amount of solar energy passing through, or impinging on, an area. Direct ambient sunlight or “one sun” of flux is equal to about 1 kW per square meter (kW/m^2). Power towers generate regions of high solar flux near the tower/receiver as the reflected rays from multiple heliostats converge on the receiver. The receiver has a special surface coating that promotes efficient absorbance of sunlight. This coating makes the receiver appear black. However, when exposed to high solar flux, the receiver will glow due to the small fraction of sunlight that is not absorbed. In addition, one can often see scattered light from the reflected beams of the solar field due to a small amount of scattering from dust or other tiny particles in the air. This gives rise to the glow or cloud of light seen around power towers during certain phases of operation (Figure 3).

FIGURE 3 Glow of Scattering Sunlight from Heliostat Beams Converging on a Point Near the Tower During Operation of the Solar Two Demonstration Plant in 1996 (Photo credit: NREL)

At the solar receiver, flux levels can reach near 1,000 kW/m^2, or about 1,000 suns, and the flux drops off as one moves away from the receiver. Any object (e.g., receiver pipe, dust particle, bird) exposed to solar flux will absorb energy and be affected by that energy based on the object's size and optical properties (dark objects absorb sunlight better than light objects), its mass and thermal heat capacity (how much absorbed energy is required to generate a temperature increase), and its duration in the flux zone. The air temperature itself is virtually unaffected except in the immediate vicinity of the receiver. This is because air absorbs very little of the solar energy, and only air directly contacting the receiver is heated to any significant degree.

The amount of solar energy absorbed by an object in the region of solar flux can be calculated based on the area of the object exposed, intensity of the light, absorptivity of the object, length of exposure time, and mass of the object. However, predicting the amount of energy absorbed by a bird flying through the solar flux region is difficult given the variability of these many factors.

BrightSource Energy and the USFWS have performed preliminary tests on the effect of sunlight or heat, respectively, on bird feathers. As presented at the California Energy Commission (CEC) Joint Workshop held August 28, 2012 (BrightSource 2012), the BrightSource study indicated no observable effects on feathers exposed to 50 kW/m^2 of solar flux for 30 seconds. Higher flux levels caused visible effects within 20 to 30 seconds. The USFWS work, reported in Kagan et al. (2014), exposed feathers to hot air for 30-second durations. Visible effects were noted starting at temperatures of 400°C. Recall that air temperature in a zone of high flux is virtually unchanged from ambient conditions. Rather, these combined results suggest that the feathers themselves absorb sufficient energy during the 30-second test to reach a temperature sufficient to cause damage. Although these results are preliminary, they suggest that zones with flux greater than 50 kW/m^2 represent the region of concern for flux effects on birds. The actual effect on a given bird depends on a number of variables, including flight path, species, ambient conditions, and light intensity; further study is necessary to understand and refine this hazard threshold.

The following analysis of the flux profile in the vicinity of an operating power tower uses 50 kW/m^2 as a representative value.

5.3 POWER TOWER FLUX MODELING

Intense solar flux produced by reflected and concentrated sunlight has been documented to harm flying birds. For this report, NREL modeled a representative power tower based on the default molten-salt power tower provided in NREL's free System Advisor Model (SAM) (https://sam.nrel.gov/). The task required developing a methodology for generating solar flux maps not only at the receiver itself, but also in the airspace surrounding the receiver. These results and subsequent analysis using this methodology will be used to understand issues related to avian fatality connected with CSP power tower technology and potentially identify operating methodologies that may reduce the threat.

5.3.1 Description of Methodology

Two NREL-developed modeling tools, SolTrace (Wendelin 2003) and SolarPILOT, were used to generate flux contour maps for the default 100-MW$_e$ molten salt power tower found in SAM (version release date 2014-01-14). The default SAM power tower case is intended to be representative of commercial technology, but is not designed to mimic a specific CSP project. Similar analyses could be performed for other sizes of towers, but are beyond the scope for the purposes of this report. The default case assumes a cylindrical receiver and a surround field (heliostats surrounding the tower). An NREL developed power tower design tool, SolarPILOT, was used to construct an optimized solar field layout based on the SAM default conditions. The field layout is shown in Figure 4. The default power tower field is symmetric about the north-south direction. This is different from many existing and planned power towers, which often have nonsymmetric field layouts due to the effects of the surrounding terrain or proximity to neighboring power tower fields. The height and diameter of the receiver for this case are 20.41 m and 17.67 m, respectively. The optical height of the tower (defined by the distance from the ground to the center of the receiver cylinder) is 203 m. The default location for the power tower is Daggett, Calif., at an elevation of 588 m, latitude of 34.9 degrees, and longitude of −116.8 degrees. The following analysis was generated using weather file data for March 20 at noon (spring equinox) and assumed the DELSOL3 insolation model (Kistler 1986). The default heliostat size is 12.2 m by 12.2 m, divided into eight panels, each canted and focused at the heliostat slant range (heliostat to receiver straight-line distance). The example shown here is representative; the methodology could be employed for any solar field configuration.

The SAM-default heliostat-aim-point algorithm was used. Heliostats are always aimed at the center axis of the receiver. Heliostats distant from the tower deliver the largest images and are aimed, for the most part, at the vertical center of the receiver. (Because the heliostat mirrors are not perfect reflectors, the reflected image spreads with distance from the heliostat.) As the distance from the heliostat to tower decreases, heliostat images get smaller, and individual heliostats can be aimed to achieve the most uniform flux from top to bottom of the receiver. This algorithm, known as "Image Priority," vertically distributes individual heliostat images along the receiver height as a function of the image size. The exact aiming strategy used for operating power towers is proprietary but is assumed to be some variation of this algorithm.

Three different cases were analyzed: a full-load condition and two full-standby conditions. Full load implies that all heliostats, up to the rated power of the receiver, are targeted at the receiver. The full load condition used Image Priority aiming. The full-standby condition (all heliostat images removed from the receiver) was analyzed for Image Priority and Centerline aiming. Centerline aiming will be discussed in more detail in following sections. The full-load and full-standby cases bound the problem for purposes of this study. During daily startup, full standby may be used while other parts of the plant are start-up before initiating receiver warm-up. To heat the receiver tubes during transitions like preheating prior to establishing salt flow and during cooldown, a small subset of the heliostat population is used to preclude thermal shock from the sudden injection of salt flow, or to prevent freezing before draining is complete.

5.3.2 Results: Full-Load Case

Using the described SAM default power tower and aiming conditions for full load, SolarPILOT was used to generate flux maps for a series of expanding cylindrical surfaces surrounding the receiver and tower. The diametric range of these cylindrical surfaces extended from 20 m (just slightly larger than the receiver diameter) to 820 m. SolarPILOT generated flux map data for each of these cylindrical surfaces. Visual Basic Excel code was then written to post-process these data for purposes of developing maps of the solar flux (kW/m^2) on vertical planes in both the north-south and east-west directions. A map of the maximum flux as a function of position relative to tower, as viewed from above the field, was also produced. Contour levels of 2.5, 5, 10, 25, 50, and 150 kW/m^2 were used in all cases. Other analyses discussed in this report suggests that 50 kW/m^2 may be a threshold flux level of concern for birds; thus, special attention was given to that contour line.

It should be pointed out that the spillage (i.e., flux that misses the receiver and extends beyond it) was not quantified in this analysis. However, because of the divergent nature of this flux and the fact that spillage is designed to be minimal (< 2%) under operating conditions, flux levels are expected to be very small (as noted in a prior analysis [BrightSource 2012]). In future work, especially looking at standby aiming scenarios, it is recommended that spillage issue be addressed.

A map of the flux contours on the north-south plane, as seen from the east, is shown in Figure 5. Because there are more heliostats to the north (see Figure 4), constant flux levels extend farther from the receiver on the north side than on the south side. To the north, the 50-kW/m^2 level ends approximately 130 m from the receiver and 178 m from the ground. To the south, the 50-kW/m^2 zone extends only about 50 m from the receiver centerline.

Figure 6 is a map of the maximum flux in the vertical direction as a function of compass position. The “wavy” contour lines in Figure 6 occur because certain directions experience higher heliostat density with distance from the receiver.

5.3.3 Results: Full-Standby Cases

Two aiming scenarios were analyzed as full-standby cases. A common aiming algorithm used in standby conditions is to aim heliostats tangentially to a virtual cylindrical surface with the same height but somewhat larger diameter than the receiver (e.g., Ho et al. 2014). There could be numerous variations to this simple strategy, such as in the diameter of the virtual cylinder, the vertical aiming strategy on this surface, and whether all heliostats are rotated such that the aim-points are in the same direction (clockwise or counterclockwise). For purposes of this analysis, a 50-m-diameter cylindrical surface was assumed. The SAM-default receiver diameter is 17.67 m, so this cylinder is considerably larger than the receiver. Visual Basic Excel code was written to transform the heliostat aim-points so that all heliostats are aimed tangentially to this virtual cylindrical surface. A counterclockwise aiming strategy for all heliostat aim-points was assumed. SolTrace was used to verify this new aiming strategy (Wendelin 2003). Figure 7 is a ray-trace graphic showing rays incident on the virtual cylindrical surface as seen from above. The receiver is noted by the red circle. Note the counterclockwise direction of incident rays on the cylinder.

In the vertical direction, two different aiming components were considered. The first placed all the aim-points at the midpoint waist of the cylindrical surface (i.e., centerline). The second maintained the vertical components of the heliostats using Image Priority aiming (vertical smoothing of the flux). If one wishes to reduce the region of high flux, the second aiming strategy should result in a slightly lower peak flux than would the centerline aiming method.

Table 8 lists the peak flux values for the three cases. Full-load aiming generates the highest flux levels in the immediate vicinity of the receiver. Changing the full load aiming would impact power production from the plant. The two different full-standby modes have lower peak fluxes than full-load mode has, and Image Priority aiming shows lower peak flux than Centerline aiming. In addition, the airspace volume of flux less than 50 kW/m^2 is somewhat reduced with Image Priority aiming. While overall this is not a huge reduction, it does suggest that in partial- or full-standby operation, a variety of approaches could be used to reduce the size of this critical flux zone. These include further broadening of the flux in the vertical direction and/or varying the size of the virtual cylinder used in tangential aiming. A randomization of heliostat aim-points could also be employed, which could significantly reduce peak flux zones. Initial indications from one such trial used an aim point strategy that limited flux to less than 5 kW/m^2. In the weeks following this practice zero avian fatalities due to high flux were reported. In summary, any alternative standby aiming methodology should be designed to reduce the peak flux as well as the volume of airspace with flux exceeding the desired minimum threshold level, while at the same time minimizing negative impacts on plant operations. This analysis identifies a range of options that might accomplish these objectives. Further investigation is needed to identify the most attractive options.

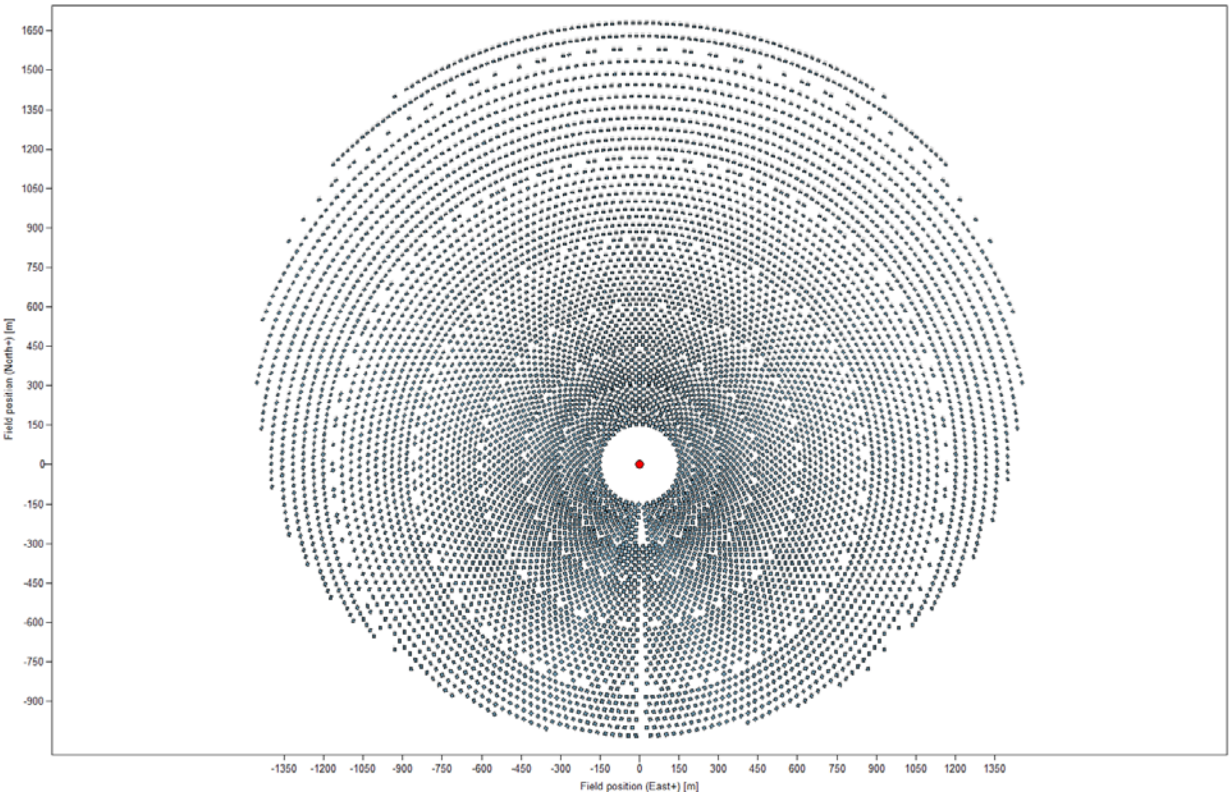

FIGURE 4 SAM Default 100-MW Molten Salt Power Tower Field Layout

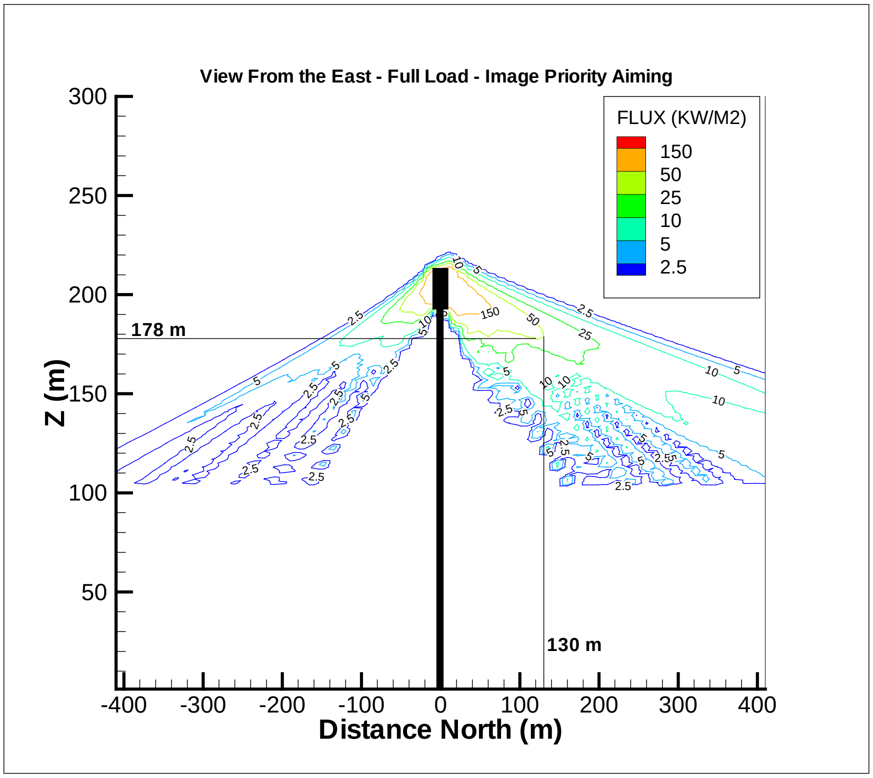

FIGURE 5 Full Load Flux on the North-South Plane as Seen from the East

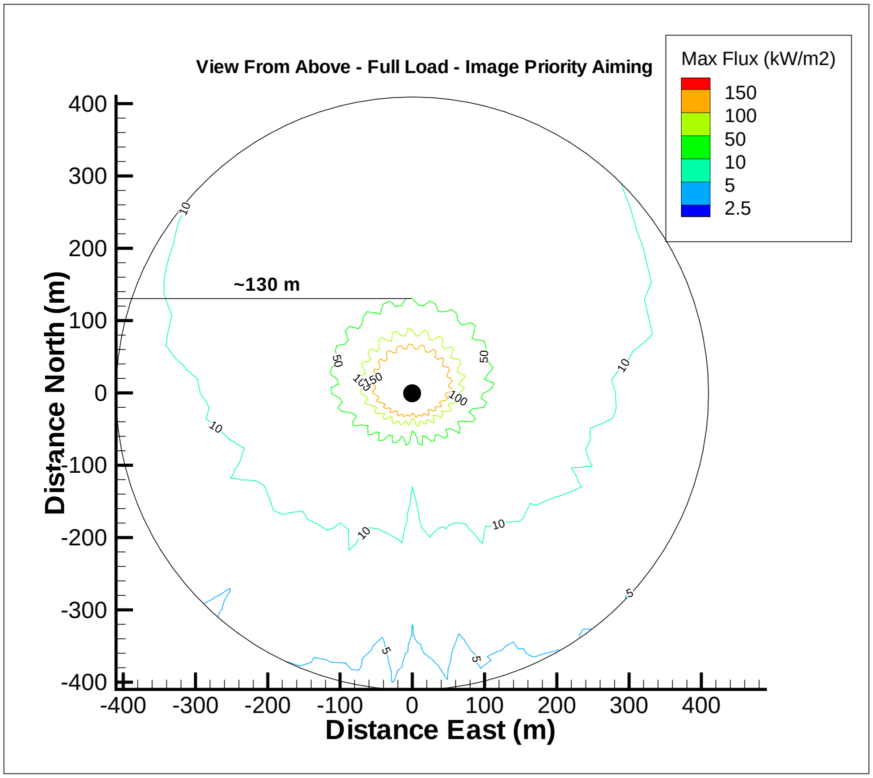

FIGURE 6 Maximum Full Load Flux as Seen from Above the Field

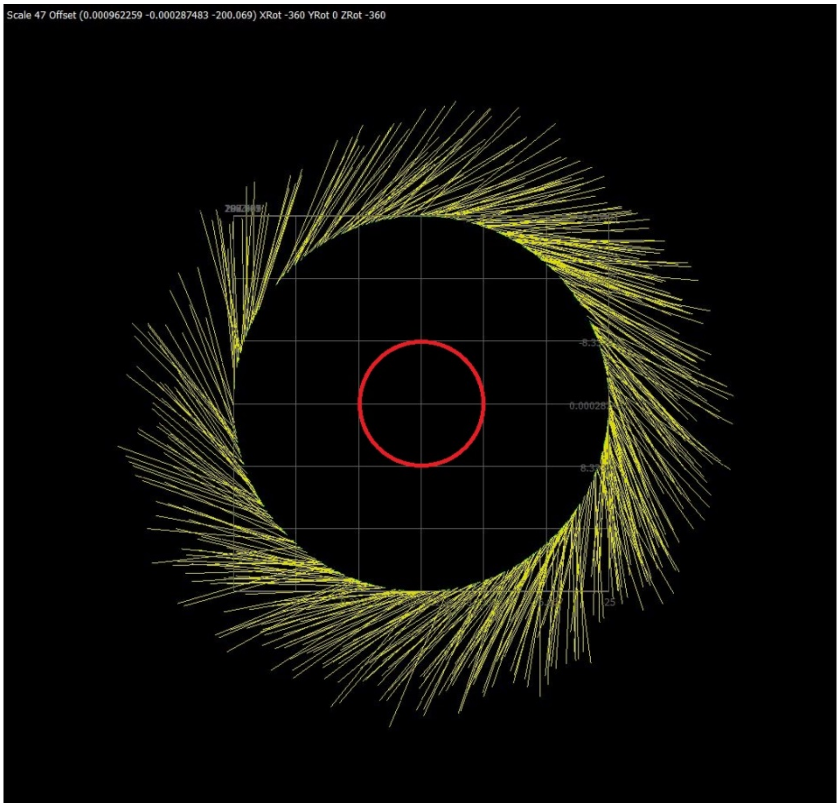

FIGURE 7 SolTrace Ray Trace of SAM Default Field Layout Showing Counterclockwise Tangential Aiming on 50-m-Diameter Virtual Cylindrical Surface. (The diameter of the actual receiver [red circle] is about 18 m.)

TABLE 8 Peak Flux Values for One Full Load and Two Full-Standby Cases[a]

Case	Peak Flux (kW/m^2)
Full Load – Image Priority Aiming	1,013
Full Standby – Centerline Aiming	665
Full Standby – Image Priority Aiming	430

[a] During full load, the peak flux is incident on the solar receiver. A switch to Image Priority aiming during full standby leads to a 35% decrease in peak flux that is generated near the receiver. The results suggest that alternative aiming strategies can be used to decrease the hazard presented by solar flux during standby.

6 SUMMARY, CONCLUSIONS, AND RECOMMENDATIONS

6.1 SUMMARY AND CONCLUSIONS

6.1.1 Avian Fatality Issues and Study Methodology

Avian fatalities have been documented at solar energy facilities employing both PV and CSP technology types. Several federal and state regulations apply to the protection of birds at solar energy facilities. Most birds are protected by the Migratory Bird Treaty Act, which prohibits the taking, killing, possession, transportation, and importation of migratory birds, their eggs, parts, and nests, except when authorized by the USFWS. Projects are also required to comply with state and federal regulations to protect threatened, endangered, and sensitive species (e.g., ESA, Bald and Golden Eagle Protection Act, BLM policy, and state wildlife codes). Mortality risks to threatened, endangered, and sensitive bird species are related to solar energy project size, location, and technology. Because the potential for impact to birds and their populations depends largely on project size and location, specific requirements for threatened, endangered, and sensitive bird species are often considered on a project-specific basis.

Like many industrial developments, utility-scale solar has the potential to impact birds and bird communities in a number of ways. There are two general types of direct solar-related bird fatality—collision-related and solar-flux-related. Collision-related impacts may occur for all types of solar energy technologies. The effects of solar flux on birds have been observed only at facilities employing power tower technologies.

Not all utility-scale solar energy developments in the United States are required to prepare and comply with project-specific avian monitoring protocols. If determined necessary through the project-specific environmental review process, as part of the solar energy applicant's required measures to reduce impacts, a BBCS may be prepared to better understand bird activity and abundance in the vicinity of a proposed solar energy project and minimize bird mortality risks. The BBCSs provide guidelines on the collection and reporting of avian fatality data, which may be incidental or systematic in nature. Despite efforts to obtain data and information from U.S. and international solar energy companies and organizations, little solar energy project-specific information on bird monitoring or fatality is publicly available.

6.1.2 Existing Avian Fatality Data and Associated Limitations

Evaluating patterns of avian fatality and mortality rates is important in order to understand bird mortality risk at solar energy facilities and in the context of risk from other energy developments. Based on results of data acquisition efforts, avian fatality data were available for seven solar energy facilities in the United States. Of these solar energy projects, systematic avian fatality data were available for four projects (only incidental data were available for the other three facilities). It is important to note that the synthesis of avian mortality in this report was based on publicly available data or information obtained through requests from solar energy companies and regulatory agencies. The information evaluated in this report does not constitute all the data that have been collected at U.S. and international solar energy facilities.

Standardization of data collection and methodology is essential to make avian mortality comparisons between projects and across industries. However, based on the paucity of existing information at solar energy facilities, it is not possible at this time to develop a solar industry-wide avian mortality estimate with any scientific certainty to make any conclusions about the risk of avian mortality at solar facilities compared with other industries and human developments. Additional systematic fatality data at solar energy facilities would be needed to better understand avian mortality risk at solar facilities.

In addition, certainty in mortality estimates will be improved through the development of standardized methods to account for the following factors that may bias mortality calculation: searcher efficiency, search effort, predation and scavenging, and the role of background mortality.

The majority of birds found killed or injured at solar facilities in southern California were passerines. The cause of death could not be determined for the majority of bird deaths, and many detections consisted only of feather spots. It has been hypothesized that feather spots found near perching/roosting structures may be incorrectly classified as fatalities when in fact they are the result of preening (WEST 2014). Feather spots may also represent predation events and not reflect direct solar-related fatality. At sites where a large proportion of the fatalities detected are identified on the basis of feather spots, assigning fatalities to a known cause of death such as predation is difficult. Further work is needed to develop standardized protocols for evaluating feather spot detections and assigning carcasses to causes of death at solar energy facilities.

On average across the six projects evaluated, approximately 54.4% of the known fatality detections were collision-related. The second-ranked cause of fatality among the six solar energy projects was predation. Approximately 26.9% of the known fatality detections were attributed to predation trauma, which may or may not be attributable to the facility. At power tower facilities (ISEGS and California Solar One), the percentage of solar-flux-related fatalities ranked higher than the percentage of predation-related fatalities, likely because birds affected by solar-flux are more easily identified by evidence of singeing.

Water-dependent species (loons, grebes, rails, coots, shorebirds, waterbirds, and waterfowl) have been postulated to be vulnerable to fatality at PV facilities because of the potential for them to confuse arrays for bodies of water (the lake effect hypothesis) (Kagan et al. 2014; WEST 2014). However, there was no consistent pattern of fatality by taxonomic groups among the solar energy facilities evaluated in this report to support or refute the lake effect hypothesis within the southern California region. Water-dependent species represented 11.3% of all recorded fatalities (as of December 2014), but there was high variability among PV facilities, with mortality ranging from 0.27% to 46.3%. Due to the limited and inconsistent dataset (i.e., six studies of incidental and systematic observations), it is too speculative to make any conclusions about the influence of the lake effect fatality of water-dependent birds. The activity and abundance of water-dependent species near solar facilities may depend on other site-specific and regional factors (such as the surrounding landscape) that have not yet been investigated (WEST 2014). Additional studies are needed to determine whether water-dependent species are especially vulnerable to fatality at PV facilities.

BBCSs from 10 solar energy projects were reviewed to present the current state of measures to minimize avian impacts at utility-scale solar energy facilities. There was variability among BBCSs in terms of ESA requirements for federally listed species, plans to conduct preconstruction baseline surveys, analytical methods, and documented mitigation measures and BMPs. In general, BBCS details were project-specific, managing the potential risks to birds and bird communities specific to the project's size (footprint), location, and technology.

6.1.3 Mitigation Measures and Best Management Practices Used in Other Industries

The availability and implementation of mitigation measures and BMPs to reduce impacts on wildlife, with a particular focus on bird and bat species, vary widely across human activities. Voluntary federal and state guidelines, ABPPs, and BBCS plans have been developed and implemented for many wind energy projects, in an industry that has experienced significant capacity additions since 2007. The emerging utility-scale solar industry could benefit, as well, from greater certainty about what assessments to conduct before, during, and after the construction of a solar project. Voluntary guidelines could prove to be quite useful as the industry expands. Several of the companies that are involved in utility-scale solar energy projects also develop wind energy projects, and some participated in the WEG development process. The WEG process was complex and took approximately seven years to complete. If federal guidelines are anticipated, a plan for a more streamlined process would benefit all parties.

In an effort to reduce electrocutions and collision fatalities at electric utility power lines, the APLIC, formed in 1989, developed voluntary BMPs that serve as a valuable knowledge base. Many of these BMPs will apply to utility-scale solar projects.

Collisions between birds and planes at airports can have significant safety and cost implications. The FAA has an active R&D program, but does not appear to have specific BMPs developed for addressing collisions with planes. Developed together with the U.S. Department of Agriculture, the *Manual for Airport Personnel* addresses a wide range of issues that may be encountered at an airport. The International Bird Strike Committee has also published BMPs, in large part based on FAA/USDA manual. Some of the strategies contained in the FAA R&D program may be applicable to addressing adverse bird and bat impacts occurring at utility-scale solar facilities.

The USFWS's WEG serve as the basis for the development of many ABPPs that are currently in use for wind energy projects. Following the tiered approach of the WEG, project-specific ABPPs are adapted to meet species- and habitat-specific considerations. In some cases, mitigation strategies have been implemented and research on the efficacy of these strategies (Tier 5) is ongoing. It is important to distinguish between post-construction monitoring utilizing scientifically rigorous and tested approaches (Tier 4), and R&D that is typically conducted within Tier 5. Ideally, the results from these Tier 5 activities should be made publicly available, preferably published in peer-reviewed journals.

A rush to require project developers to implement untested or unfounded mitigation strategies distracts from the opportunity to conduct scientifically rigorous research and contribute to the knowledge base to provide meaningful solutions. For the solar industry, participating in research to address wildlife impact challenges in the early stages of the growth of this energy sector may help avoid situations that the wind industry experienced, in which informative research was delayed or conducted under study designs that did not adequately address the issues.

6.1.4 Technology-Specific Factors Potentially Associated with Avian Fatality

Power towers are the only technology that has noted solar-flux-related avian fatalities. This report developed a flux-mapping methodology using SAM, SolarPILOT, and SolTrace to predict solar flux in the vicinity of a power tower receiver under full-load and full-standby modes. The method allows exploration of the effects of alternative aiming strategies on peak flux, as well as the airspace region exceeding specified threshold flux levels. These preliminary results compare well with previous analyses and suggest that various approaches to standby aiming could significantly reduce flux levels and their impact on avian fatality. Future work is recommended to determine the impact alternative aiming strategies have on plant operations, and to seek solutions that simultaneously minimize negative impacts on plant operations and zones of high flux that may be harmful to flying birds.

6.2 RECOMMENDATIONS

On the basis of the findings presented in this report, several recommendations can be made to improve understanding of avian fatality issues at utility-scale solar energy facilities. There is a basic need to understand the cause of fatalities (e.g., predation, collision, flux) associated with solar arrays and other infrastructure. Observations of available BBCSs at utility-scale solar facilities revealed opportunities to improve consistency and standardization in avian monitoring protocols. Not all utility-scale solar energy developments in the United States have been required to prepare and comply with project-specific avian monitoring protocols, particularly those projects located on private lands. Building upon lessons learned from the wind energy industry, a programmatic guideline similar to the WEG may help promote standardized monitoring and data collection throughout the solar energy industry. Adopting applicable guidelines from the WEG would help promote compliance with relevant wildlife laws and regulations and encourage scientifically rigorous survey, monitoring, assessment, and research designs proportionate to the risk to species of concern. Further, they should produce potentially comparable data across the nation and mitigate (including avoid, minimize, and compensate) for potential adverse effects on species of concern and their habitats.

The following should be considered when developing standardized inventory and monitoring protocols at utility-scale solar energy facilities:

- Distribution of habitat, species, and resources on the site and in adjacent areas
- Importance of project area relative to local, landscape, and region
- Resident and migrant use of site and surroundings
- Seasonal patterns of use
- Daytime versus nighttime effects
- Effects of project on resident and migratory species
- Direct, indirect, and cumulative effects
- Role of predators in carcass persistence and transport (on and off the facility)
- Distance effect (zone of influence)
- Background mortality rate
- Mortality rates attributable to project features
- Contributors to risk (technology and project feature-specific)
- Role of confounding factors (e.g., moon phase, weather)
- Use of indicator species to represent different categories of species
- Focus on statistically robust data collection rather than incidental or ad hoc reporting

Additional systematically collected fatality data at other solar energy projects in multiple regions would be needed to better understand avian mortality risk at solar facilities compared with other energy developments. More systematic study of utility-scale solar facilities is needed in order to make conclusions about avian risk and mortality, types of birds impacted, contribution of background mortality to mortality estimates, influence of facility attraction to birds (e.g., lake effect), and other factors such as predation could be improved through the development of standardized monitoring methodologies and assessment approaches.

The opportunity exists for the development of a science plan to focus future research on systematic data collection to better understand impacts, causal factors, and feasible mitigation measures and BMPs to inform future decisions about solar energy project siting and design. Such science plans should focus on uncertainties related to avian risks and causative factors, population-level impacts to migratory birds, development of more effective inventory and monitoring techniques, and guide the development of pilot studies to assess the implications of mitigation measures and BMPs to energy production.

Moving forward, the industry, federal and state agencies, and other stakeholders might all benefit from working collaboratively towards (1) developing and implementing useful and scientifically rigorous data collection program, (2) evaluating avian mortality related to utility-scale solar development and the causal effects, and (3) identifying appropriate mitigation measures to address identified issues.

APPENDIX A:

Glossary

APPENDIX A:

Glossary

Adaptive Management – A structured, iterative process of robust decision making in the face of uncertainty, with an aim to reduce uncertainty over time via system monitoring. The goal is to decrease avian mortality — Deterrence and BMPs are tested in this framework and monitored to determine whether they are efficacious.

Best Management Practices (BMPs) – Practices the facility can undertake (such as panel or mirror positioning) to decrease risk/impacts to species.

Carcass Removal/Scavenging Rates – The probability that a carcass will be removed before a searcher has the opportunity to observe it. Often described as the mean number of days that a carcass will remain before being scavenged.

Compensatory Mitigation – The provision of compensatory land/monetary or other actions that are intended to offset the impacts of the action.

Concentrating Solar Power (CSP) – A system which captures solar energy as heat before converting it into electricity by a thermo-electric power cycle.

Deterrent – A measure used to repel avian species from a site, such as bird spikes or auditory/chemosensory repellents.

Direct Impact – An impact observable within the solar project footprint resulting from ground-disturbing activities or operation of the project.

Fatality – Death or the occurrence of death.

Feather Spot – Feathers concentrated together in a small area and considered an avian fatality. Feather spots have been defined as two or more primary flight feathers, five or more tail feathers, or 10 or more feathers of any type concentrated together in an area of 1 square meter or smaller. The definition can vary among studies.

Incidental Data – Fatalities observed incidentally during other activities that were not part of focused systematic searches for carcasses.

Indirect Impact – An impact that may extend beyond the solar project footprint.

Lake Effect Hypothesis – The hypothesis that water-dependent bird species may potentially mistake the extensive solar arrays for water features on which the birds can land, usually at night. Such collisions, often do not result in direct mortality, but the birds sometimes cannot take off after collisions because they are adapted to take off from water, not dry land.

Mitigation – A broad category of measures/techniques used to decrease or avoid impacts (includes BMPs).

Monitoring – Studies designed to determine mortality at sites.

Mortality – The relative frequency of deaths in a specific population (death rate).

Photovoltaic (PV) – A system that converts sunlight directly into electricity.

Searcher Efficiency – The probability that a searcher will find a carcass during a systematic survey.

Solar Flux – A measure of the amount of solar energy passing through, or impinging on, a specific area.

Systematic Data – Fatalities observed during the course of dedicated search efforts.

Utility-scale – Loosely defined as ground-mounted facilities larger than 1 megawatt that are tied directly to the transmission grid.

Water-Dependent Species – Bird species dependent on aquatic habitats to complete portions of their life cycles (shorebirds, marshbirds, wading birds, seabirds, and waterfowl).

APPENDIX B:

Summary of Avian Fatality Data and Monitoring Plans Developed for Utility-Scale Solar Facilities

APPENDIX B:

Summary of Avian Fatality Data and Monitoring Plans Developed for Utility-Scale Solar Facilities

B.1 Summary of Avian Fatality Data

Table B.1 presents a summary of avian fatality data collected at utility-scale solar facilities in the U.S. All facilities reported in this table are located in southern California. This table serves as a summary of all reported avian fatality observations at seven utility-scale solar facilities between 2011 and 2014. The data presented in Table B.1 were collected over various time periods and monitoring intervals. Fatality observations at the solar facilities were not based on consistent survey approaches and include incidental and systematic observations.

TABLE B.1 Summary of Avian Fatality by Species for Seven Solar Energy Facilities in the United States for the period 2011-2014. Observations were recorded at solar facilities from various monitoring periods and includes results of incidental and systematic surveys.[a]

[b] Considered to be a resident near the Ivanpah facility and a migrant near the Genesis facility.

[c] Considered to be a resident near the Ivanpah facility and a migrant near the Genesis and Solar One facilities.

B.2 Summary of Avian and Bat Protection Plans at Utility-Scale Solar Facilities

This section presents an overview of existing avian fatality monitoring and reporting requirements and related BMPs (e.g., mitigation or conservation measures), as identified in available solar project-specific ABPPs. The purpose of this section is to present the current state of measures to minimize avian impacts at utility-scale solar energy facilities. A summary of solar facility ABPPs is provided in Table B.2. Monitoring measures and BMPs employed in other applications are discussed in Section 4.

On the basis of efforts to collect data and information described in Section 2.2, BBCSs or similar avian monitoring plans (hereafter, all such plans are referred to as “BBCSs”) were available for the following 10 solar energy facilities:

- Centinela
- Crescent Dunes
- Desert Sunlight
- Genesis
- Ivanpah Solar Electric Generating System (ISEGS)
- Palen Solar Electric Generating System (PSEGS)
- Rice Solar
- Silver State North
- Silver State South
- Topaz Solar Farm

Each monitoring plan was reviewed to identify measures used to monitor, analyze, and report avian fatalities. The following aspects of each plan were reviewed:

- The documented presence of threatened or endangered species listed under the ESA and specific monitoring requirements for those species;

- Plans to conduct pre-construction baseline surveys for bird activity and abundance;

- Analysis methods (models used, experimental design, methods, etc.); and

- Documented avoidance, minimization, and mitigation measures and BMPs.

TABLE B.2 Summary of Avian and Bat Protection Plans at Utility-Scale Solar Facilities

Project	Silver State South	Crescent Dunes	Genesis	Rice Solar	Topaz	Silver State North	Palen (PSEGS)	Ivanpah (ISEGS)	Desert Sunlight	Centinela
State	NV	NV	CA	CA	CA	NV	CA	CA	CA	CA
Technology	PV	Power tower	CSP - parabolic trough	Power tower	PV	PV	Power tower	Power tower	PV	PV
Acres	2,427	2,950	1,950	3,324	3,500	7,925	3,794	3,600	4,410	2,067
Year	2013	2011	2014	2011	2011	2011	2014	2013	2010	2012
ESA requirements	No ESA-listed species were described.	No ESA-listed species were described. However, the document mentions that all avian and bat species that are listed as threatened or endangered species will be protected.	No ESA-listed birds were documented in the study area.	No ESA-listed species were described. However, the document mentions that all species identified as rare, threatened, or endangered by the ESA and CESA will be protected.	No ESA-listed birds were documented in the study area.	No ESA-listed bird species were described. However, ESA Section 7 consultation for the desert tortoise was described.	No ESA-listed species were described. However, the document mentions that the BLM will coordinate with the USFWS to ensure that the plan meets ESA requirements.	No ESA-listed species were described. However, the document describes methods to conserve any state- and federally listed species observed on the site.	No ESA-listed bird species documented in the study area. The document discusses other state-listed and sensitive bird species.	Two ESA-listed bird species were discussed (southwestern willow flycatcher and Yuma clapper rail). Through ESA consultation with the USFWS, it was determined that the solar energy development “May affect, but not likely adversely affect” either species.
Baseline surveys	Yes	No pre-construction baseline surveys were reported.	Yes	Yes. Baseline surveys will be conducted before construction activities begin.	Yes	Yes. Surveys will be conducted to determine the presence of special-status and nesting birds.	Yes	No pre-construction baseline surveys were reported.	Yes	Yes
Number of monitoring years	4 (2010–2013)	NA[a]	3 (2007–2010)	NA	2 (2008–2010)	No formal pre-construction avian surveys have been conducted in the project area	2 (2013–2014)	2014-2015	1	2 (2009–2011)
Number of years/seasons of baseline monitoring	• 2010 (spring) - Golden Eagle Aerial Surveys; • 2011 (spring), 2012 (spring, fall) - Burrowing Owl Surveys; • 2012 (spring, fall), 2013 (winter, spring) - Avian Point Counts; • 2012 (winter, spring, fall), 2013 (winter, spring) - Golden Eagle Point Counts; • 2012, 2013 (winter, spring, fall) - Common Raven Point Counts; • 2013 (throughout breeding season) - Golden Eagle Nest Monitoring	NA	• Spring and winter 2009 avian point count surveys; • Golden eagle nest surveys: March 25–26 and April 2–3, 2010; March 23–24 and May 5–7, 2011 (2011 survey conducted for a different nearby project). • Western burrowing owl surveys: Phase I Habitat Assessment December 2007; Phase II burrow location 2009; Phase III breeding-season surveys spring 2009.	NA	• Nesting, wintering, protocol, and general bird surveys: March 2008–July 2010. • Aerial survey for golden eagle nests: 2010	NA	• Bird use count surveys: April–June 2013, August–December 2013, March–June 2014 • Small bird count surveys: April–June 2013, August-November 2013, March–June 2014 • Gila woodpecker surveys: April–June 2013 • Elf owl surveys: May–June 2013 • Habitat evaluation for elf owl and Gila woodpecker: July 2013 • Golden eagle surveys: March–August 2013, April–August 2014 • Golden eagle prey abundance surveys: April–June 2013	NA	Point count surveys - April– May 2010. Golden eagle surveys - April 2–3, 2010 and May 14, 2010. Data analysis	No detailed discussion of data analysis.	Two primary analyses would be conducted. The first would use the program DISTANCE to determine the most effective transect width to search for carcasses. The second would use the program MARK to estimate the total number of fatalities controlling for detection rate, scavenging rate, and proximity to the power tower.	To calculate the project-wide mortality rate (fatalities/MW/year) and the total project fatalities, using a mortality estimator (Huso 2011 or other appropriate statistical methods (e.g., Warren-Hicks, Komer-Nievergelt).	No detailed discussion of data analysis.	Bird utilization rates to be used in combination with bird mortality rates to calculate a Bird Risk Index. The Bird Risk Index would be used to identify project components that may require Adaptive Management and to assess those components that are successfully operating without impacts to birds.	No detailed discussion of data analysis.	Analyses will include preliminary adjusted mortality estimates, breakdown of fatalities by taxonomic group, resident or migratory status, location of fatality (e.g., tower, heliostats, road), and suspected cause of death (e.g.,. collision, flux). In addition, maps will be provided to display the spatial distribution of fatalities by taxonomic group and suspected cause of death. Gives a formula for determining overall mortality.	The total number of avian casualties will be estimated by adjusting for search frequency, removal bias (length of carcass persistence in the field), and searcher efficiency bias (percentage found).	No detailed discussion of data analysis.	Two primary analyses will be conducted. The first will use the program DISTANCE to determine the most effective transect width to search for carcasses. The second will use the program MARK to estimate total number of fatalities controlling for detection rate, scavenging rate, and proximity to project components.
Adaptive management	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes
Avoidance/ minimization/ mitigation measures	Measures include: • Avoidance of: locations with federally or state-listed sensitive species and areas frequently used by birds and their nesting areas; • Reduce noise impacts; • Avoid using lattice-type structures to minimize perching and nesting; • Avoid use of guy wires; • Focus facility lights downward (light management); • Place electric lines underground; • Avoid creation of roads; • Place netting over evaporation ponds (if needed).	Measures include: • Minimize lighting; • Construct evaporation ponds in a manner to discourage wading; • Install anti-perching devices at evaporation ponds; • Install visual deterrents; and • Avoid land-clearing activities.	Measures include: • Minimize perching and nesting opportunities; • Bury telecommunication lines to minimize the risk of bird collisions; • Increase visibility of aboveground transmission lines to reduce collisions; and • Minimize lighting.	Measures include: • Limit disturbance areas and perimeter fencing, minimize road and traffic impacts; • Minimize impacts of transmission alignments; • Avoid use of toxic substances; • Minimize lighting and noise impacts; • Avoid wildlife pitfalls; • Minimize standing water; • Implement worker guidelines; • Implement erosion control measures; • Monitor ground-disturbing activities; and • Regulate fugitive dust.	A suite of measures are provided to minimize project conflicts with birds and bats, protect birds and bats from harm due to construction and operation of the project, and enhance habitat in the project vicinity for birds and bats.	Measures include: • Pre-construction surveys; • Worker environmental awareness program; • Migratory birds and raptors impacts reduction measures; • Burrowing owl measures; • If eagle fatality occurs as a result of the project, First Solar will work with the agencies to identify appropriate compensatory mitigation to ensure that the no net loss standard is maintained.	Measures include: • Project design; • Worker Environmental Awareness Program; • Noise minimization; • Pre-construction nest surveys and avoidance measures; • Avian enhancement and conservation plan; • Burrowing owl Impact minimization.	Specific measures are not described. The document states that substantial resources have been committed toward the development and implementation of avoidance, minimization, and mitigation actions to benefit the conservation of avian resources[a].	Siting criteria, design features, and BMPs have been incorporated into the project that will provide significant avoidance and minimization measures into the project to reduce the potential for adverse effects on protected avian and bat species. Measures include: • Nest avoidance.	Avoidance, minimization, and mitigation measures will be implemented to avoid or minimize bird impacts during construction and operation of the project. Examples of such avoidance, minimization and mitigation measures include the following: • Designing project electric lines in accordance with Avian Power Line Interaction Committee (APLIC) design standards; • Conducting pre-construction surveys to avoid impacts on nesting birds; • Providing for the protection of suitable habitat to compensate for impacts on burrowing owl foraging habitat; • Installing flight diverters where overhead lines cross certain riparian areas; and

Section 1.0 Introduction

Through adoption of Resolution #2011-119, the Board of Supervisors of San Luis Obispo County (the County) approved the California Valley Solar Ranch Project (CVSR Project) Conditional Use Permit (DRC 2008-00097) on 19 April 2011. The Conditional Use Permit is subject to the Conditions of Approval (COAs) set forth in Exhibit 6 attached to the Resolution.

The Conditional Use Permit allows High Plains Ranch II, LLC (and any successor in interest for the life of the CVSR Project) to construct and operate a 250-megawatt photovoltaic solar power plant on an approximately 4685-acre (ac) site, located mostly south of State Route (SR) 58, about four miles (mi) east of Soda Lake Road, immediately north of the California Valley subdivision, in the Shandon-Carrizo planning area of San Luis Obispo County (CVSR site).

COA #58 of the CVSR Project Conditional Use Permit requires an Avian and Bat Protection Plan (ABPP) and a quarterly report detailing any Project-related bird or bat deaths or injuries detected during the monitoring study defined in COA #58c. To satisfy COA #58c, High Plains Ranch II, LLC, has prepared this Post-construction Avian and Bat Protection Plan Fatality Report, which documents the number of avian and bat fatalities counted during Project post-construction monitoring from 16 August through 15 November 2013.

The Project elements surveyed during this period were the Gen-tie Line; Medium-voltage Overhead (MVOH) Line; Evaporation Pond; Arrays 1, 2, 4, 5, 6, 7, 8, 9, and 11; and the perimeter fences and control plots associated with all arrays. This quarterly[1] report does not include the results of searcher efficiency trials, carcass removal trials, or data analyses, nor does it include detailed discussions. These features will be provided in the annual report.

---

[1] The quarters referred to are the monitoring quarters specified in the COA. The first four quarters were 16 August to 15 November 2012, 16 November 2012 to 15 February 2013, 16 February to 15 May 2013, and 16 May to 15 August 2013. The period covered by this report is 16 August to 15 November 2013, and the next quarter will be 16 November 2013 to 15 February 2014.

Figure 1: Project Site with Gen-tie Line, MVOH Line and Nine Arrays

Section 2.0 Methods

Fatality surveys began at varying times; the commencement dates of surveys at all sites are listed in Table 1. Fatality surveys in Arrays 1, 2, 4, 5, and 8 and along the Gen-tie and MVOH Lines began before this reporting period. During initial surveys of Array 2 in 2013 only the Serengeti portion of the array was surveyed. Fatality surveys were expanded to 100% of Array 2 once the entire array became operational. Because Array 2 North is partially composed of the Serengeti, results for the Serengeti are reported as Array 2 North. Fatality surveys at the remaining sites (Arrays 6, 7, 9, and 11; associated perimeter fences and control plots; and the Evaporation Pond) began during the current period. With exception of Arrays 1 and 2, and the Gen-tie and MVOH Lines, all Project elements were surveyed at 20% coverage for each element area. Fatalities were counted when surveyors found smudge marks and feather spots (on a solar panel) or feather spots only on the ground; fur accompanied by flesh, blood, or bone; or a carcass. Feather spots are defined as two or more flight feathers, five or more tail feathers, or ten or more body feathers. Feathers spots not meeting these requirements but containing flesh, blood, or bone were also considered a fatality. Fatalities of non-avian or non-bat taxa were documented when found, but are not discussed in this report. However, all specimens including non-avian and non-bat fatalities were reported pursuant to state and federal salvage permit requirements. Additionally, fatalities of sensitive species were reported to the California Natural Diversity Database. All carcasses and feather spots were collected during each fatality survey, except in areas that overlapped with repeat surveys in Arrays 1 and 2 (see methods for "5-day Repeat Surveys").

Table 1. Fatality Survey Start Dates by Project Element

Project Element	Date Fatality Surveys Began
Gen-tie Line	6 June 2012
Array 1	20 September 2012
Array 1 Control Plot	1 November 2012
Arrays 1 and 2 Fence	25 September 2012
Array 2 North and South	27 November 2012
Array 2 Serengeti[2]	20 September 2012
Array 2 Control Plot	30 October 2012
20% of Array 8	7 January 2013
20% of Array 8 Fence	20 May 2013
Array 8 Control Plots	4 February 2013
20% of Array 4	9 January 2013
20% of Array 4 Fence	16 January 2013
20% of Array 4 Control Plots	6 February 2013
20% of Array 5	9 January 2013
20% of Array 5 Fence	16 January 2013

---

[2] Results for Array 2 Serengeti are reported as part of Array 2 North.

Project Element	**Date Fatality Surveys Began**
Gen-tie Line	6 June 2012
MVOH Line	30 January 2013
Array 6, Fence, and Control Plots	30 September 2013
Array 7, Fence, and Control Plots	10 October 2013
Array 9 and Fence	6 November 2013
Array 11, Fence, and Control Plots	6 November 2013
Evaporation Pond	11 November 2013

2.1 Weekly Fatality Searches

Weekly fatality searches were performed for the Evaporation Pond, Gen-tie Line; MVOH Line; Arrays 1, 2, 4, 5, 6, 7, 8, 9, and 11; and the perimeter fences and control plots associated with the arrays. Each week, random start locations were selected for each Project element using a random number generator. Random selection was based on tower number (Gen-tie Line), line segment (MVOH Line), numbered array corners (Solar Arrays), and numbered fence corners (perimeter fence).

A team of two biologists surveyed an approximately 30-meter- (m-) wide transect centered under the Gen-tie Line and an approximately 18-m-wide transect centered under the MVOH Line. Each person surveyed half the transect width and half the tower or pole radial areas for the Gen-tie and MVOH Lines. For the Gen-tie Line, each person walked approximately 3 m from the outer limits of the overhead powerline and searched a 15-m-wide transect for large birds and a 6-m-wide transect for small birds and bats. For the MVOH Line, each searcher walked directly under each line segment and searched an approximately 9-m-wide transect for small and large birds, and bats.

For array searches, teams of two biologists surveyed panel trackers together. The biologists walked into every other row of panels in each tracker, visually scanning that row and each adjacent row. Safety concerns prohibited searchers from crossing the drive arm, so upon reaching the drive arm, searchers turned around and continued to scan the next row as they proceeded out of the walk space between rows. Thus, searchers physically walked every other row and visually scanned adjacent rows to ensure full coverage.

Control plots were established on adjacent onsite Conservation Lands (these lands are within 0.6 mi or 1 kilometer [km] for all arrays except Arrays 5 and 9.). Control plots were not established for Arrays 5 or 9 because the 20% survey area for these arrays contained too few trackers to meet the control plot establishment guidelines set forth in the *Avian and Bat Fatality Monitoring Plan for the California Valley Solar Ranch Project, San Luis Obispo County, CA* (one control plot per 16 trackers searched). Each control plot is equivalent to the size of two tracker blocks. Wooden stakes were used to delineate mock panel trackers on the control plots, and searchers followed the same pattern and procedure used for walking panel trackers.

Fences surrounding all Arrays were surveyed by one biologist. Each week, the biologist walked the inside portion of the fence while scanning an approximately 6-m-wide belt centered on the fence.

The Evaporation Pond was surveyed by one biologist. Each week, the biologist walked the perimeter of the pond inside the fenced area while scanning the pond and an approximately 6-m-wide belt centered on the fence. Before entering the fenced area, the biologist also scanned the pond to assess avian activity.

2.2 5-day Repeat Surveys

In addition to regular weekly searches, a series of repeat searches was conducted. These 5-day repeat surveys were designed to fulfill several functions: 1) they serve to identify a portion of the fatalities missed by regular weekly searchers, 2) they give limited estimates for the permanence of both feather spots and carcasses, 3) they provide an independent estimate of site-wide fatalities, and 4) they help to provide an estimate of carcass deposition rates. Five-day repeat surveys were conducted on all Project elements subject to regular weekly searches, with the exception of the Gen-tie Line. The Gen-tie Line was not included in the 5-day repeat surveys because it is assumed that small birds and bats are unlikely to strike high-tension powerlines. Each of the remaining sites were subjected to 5-day repeat surveys once every 4 weeks, and surveys were organized so that a 5-day repeat survey was conducted for a different site each week. Because of the size of Array 2, combining the 5-day survey effort of Array 2 Serengeti with Array 2 North and South was not feasible. Therefore, 5-day repeat surveys of Array 2 Serengeti were conducted separately from those of Array 2 North and South. Because regular weekly searches of the Evaporation Pond started at the end of this quarter, no 5-day repeats of this Project Element occurred during this reporting period.

During each 5-day repeat survey period, searchers covered the same 25% portion of a given Project element for 5 consecutive days. Repeat surveys of arrays also included searches of the perimeter fences and control plots associated with each array.

Five-day repeat surveys were originally conducted in the same areas as regular weekly searches for all arrays. In June 2013, this protocol was changed, and four new, nonoverlapping areas were established for 5-day repeat surveys in all array areas, in order to keep the search interval at a constant span of 7 days for all weekly search areas. (In Arrays 1 and 2, and along the MVOH Line, however, overlapping search areas were unavoidable because weekly searches cover 100% of these arrays.) Under the revised protocol, feather spots and scavenged carcasses were still collected on the fifth day of each 5-day repeat survey, but any intact carcasses found were treated as carcass removal trial specimens: camera traps were placed by the carcasses to record the species of scavengers that visited the carcass and to monitor the persistence of the carcass past the 5-day span of the repeat surveys. One of the four blocks was selected at random for each 5-day search period. Because the new survey blocks were established in areas that had never been searched, the first day of each 5-

day repeat survey in the new areas was treated as a clearance search, and all fatalities found on the first day were removed from further analysis. However, for Arrays 1 and 2, the MVOH Line, and any blocks searched in previous months, data for fatalities found on the first day was collected. Because the actual date of deposition was unknown, these fatalities were removed after the first day and were not used to form persistence estimates. Likewise, these fatalities will not be included in modeling annual fatality estimates.

2.3 1-Day Repeat Surveys

One-day repeats were a second type of repeat survey designed to identify a portion of the fatalities missed by weekly searchers. One-day repeat surveys covered a randomly selected block comprising 25% of each element of the weekly search areas; for example, the 1-day repeat survey of Array 8 included a search of 25% of the 20% weekly search area within the array, fence, and associated control plots. These blocks were surveyed on the day following regular weekly searches, every other week (biweekly).

One-day repeat surveys were also conducted after each 5-day repeat survey, on either the last day of the 5-day survey or 1 day after completion of the 5-day survey. These 1-day repeat surveys were conducted to provide further estimates of the detectability of small bird and bat carcasses.

Section 3.0 Results

One hundred and three avian fatalities were counted between 16 August and 15 November 2013 in the surveyed operational portions of the Project site. Eighty of the avian fatalities were counted from feather spots, and 20 were counted from whole or partial carcasses. All fatalities were mapped (Figures 2 through 6), and a summary of the fatality searches was compiled (Table 2). Eighteen avian species, plus three unidentified small birds, including one unidentified warbler , were represented in the fatalities found at all survey areas (Appendix A). Mourning doves (*Zenaida macroura*) were the most numerous fatalities observed (39), with horned larks (*Eremophilia alpestris*) (12) and savannah sparrows (*Passerculus sandwichensis*) (11) less frequently observed (Appendix A). No bat fatalities were observed during this survey period.

The Gen-tie Line and the whole of Array 2 presented the most fatalities. Most of the avian fatalities found in all survey areas were indicated by feather spots. However, a small number of whole and partial carcasses were also discovered. In solar arrays, feather spots were observed on the ground near panels, but no fatalities were observed on the panels themselves and no signs of panel strikes (e.g., smudge marks, feathers, or flesh) were observed. In the few cases in which whole carcasses were found but no injuries were apparent, the cause of death was difficult to determine.

3.1 Weekly Fatality Searches

All Project elements were surveyed weekly, with the following exceptions:

- Array 8 was not surveyed on 2 September 2013, in observance of the Labor Day holiday.
- The Array 4 fence and control plot, and a section of Array 4, were not surveyed on 9 October 2013 because of inclement weather conditions.
- The Array 5 fence was not surveyed on 23 October 2013 because of staffing issues.
- Arrays 6 and 8 were not surveyed on 4 November 2013 because of inclement weather conditions.

Because surveys were conducted only on designated days as a part of the survey protocol, if a survey day (for example, a Wednesday when the Gen-tie Line is scheduled to be surveyed) was missed due to inclement weather or maintenance access issues, another weekly survey (a “make-up” survey) was not conducted.

Table 2. Summary of Avian Fatality Searches Conducted between 16 August and 15 November 2013, and Fatality Totals[3]

Project Element	Total Fatalities	Fatalities Counted from Feather Spots	Fatalities Indicated by Evidence Other than Feather Spots, and Notes
Array 1	13	12	One partial carcasses (partial wing) with bone and feathers was found; cause of death unknown.
Array 1 control	0	0	n/a
Array 2 North	17	13	Three partial carcasses were found.
Array 2 South	8	8	n/a
Array 2 control	2	1	One partial specimen with wing, feathers, bone, and internal organs was detected.
Array 1–2 fence	1	1	n/a
Array 4	10	9	One partial specimen with wing and clumps of contour feathers was detected.
Array 4 controls and fence	0	0	n/a
Array 5 and Array 5controls, and fence	0	0	n/a
Array 6	1	0	One partial specimen with wing parts and feathers was detected.
Array 6 controls and fence	0	0	n/a
Array 7	4	4	n/a
Array 7 control	1	1	n/a
Array 7 fence	1	0	One partial specimen, with a wing and flight and contour feathers, was detected.
Array 8 Circuit 2	9	7	Two partial specimens, each with one wing and contour feathers, were detected.
Array 8 control	0	0	n/a
Array 8 fence	1	0	One whole carcass was detected.
Array 9, and Array 9 controls and fence	0	0	n/a
Array 11, Array 11 controls and fence	0	0	n/a
Gen-tie Line	29	25	Four whole carcasses and four partial carcasses, consisting of scavenged remains, were found directly under the overhead powerline. Cause of death likely powerline strike.
MVOH Line	6	5	One whole carcass was found directly under the powerline. Cause of death likely powerline strike.
Evaporation Pond	0	0	n/a
Total Fatalities	**103**		

---

[3] This table only includes fatalities detected during fatality searches. Incidental fatalities are reported in the text of Section 8.1 and Table A-1 in the Appendix.

Thirteen avian fatalities were counted in Array 1 (Table 2; Figure 2). All but one fatality were counted from feather spots. One partial specimen was indicated by a partial wing, bone, and feathers. No fatalities were observed in control plots associated with Array 1.

Twenty-seven fatalities were counted in the Array 2 elements, including Array 2 North and South and the Array 2 control plots. Seventeen avian fatalities were counted in Array 2 North (Table 2; Figure 2). Three of these fatalities were counted from partial carcasses including one feather spot from a burrowing owl (*Athene cunicularia*), a California Species of Special Concern. Eight avian fatalities were counted in Array 2 South (Table 2; Figure 2), all based upon feather spots. One loggerhead shrike (*Lanius ludovicianus*), a California Species of Special Concern, accounted for one of these fatalities. Two fatalities, one feather spot and one partial carcass, were counted in control plots associated with Array 2.

One fatality was counted from a feather spot along the perimeter fence surrounding Arrays 1 and 2.

Ten avian fatalities were counted in Array 4 (Table 2; Figure 3). Nine of these fatalities were counted from feather spots and one was counted from a specimen consisting of a partial wing and several clumps of body feathers. No fatalities were observed along the Array 4 perimeter fence or control plots.

One partial specimen, consisting of wing parts and feathers, was found in Array 6 (Table 2; Figure 3). No fatalities were observed along the Array 6 perimeter fence or control plots.

Four fatalities were counted from feather spots in Array 7 (Table 2; Figure 3). One fatality was counted from a partial specimen, consisting of a wing and feathers, along the perimeter fence surrounding Array 7. One fatality was counted from a feather spot in a control plot associated with Array 7.

Nine fatalities were counted in Array 8 Circuit 2 (Table 2; Figure 4). Seven of these fatalities were counted from feather spots and two were counted from partial specimens consisting of a wing with flesh and body feathers. One whole carcass was counted along the perimeter fence surrounding Array 8. No fatalities were observed in control plots associated with Array 8.

Twenty-nine fatalities were counted along the Gen-tie Line (Table 2; Figure 5). Four of these fatalities were counted from whole carcasses, and two were counted from partial specimens, consisting of a partial wing and body feathers and a half carcass, respectively. All 29 fatalities were found directly, or nearly directly, under the Gen-tie Line.

Six fatalities were counted along the MVOH Line (Table 2; Figure 6). One fatality was counted from a whole carcass. All fatalities were found directly or nearly directly under the MVOH Line.

Three additional fatalities, one barn owl (*Tyto alba*), one mourning dove, and one burrowing owl, were found incidentally in Array 4 and Array 9 (Table A-1). All were counted from feather spots. The burrowing owl, found in Array 9, showed signs of possibly having been scavenged by a mammal: the feathers appeared to have been chewed or sheared. No evidence of panel strike was observed in any of these incidentally observed fatalities.

No fatalities were found during regular fatality searches of Arrays 5, 9, or 11, their associated perimeter fences, their control plots, or the Evaporation Pond.

3.2 5-day Repeat Surveys

During the 5-day repeat surveys, 24 avian fatalities were observed between 16 August and 15 November 2013 in the surveyed operational portions of the Project site (Table 3, at the end of this section). Of these 24 fatalities, three were found in Array 1, one was found on the combined fence for Arrays 1 and 2, one was found in Array 2 Serengeti, six were found in Array 2 North and South, two were found in Array 4, two were found in Array 5, one was found in Array 6, three were found in Array 8, two were found on the Array 8 Fence, and two were found on the MVOH Line. No fatalities were found in any of the other arrays. No bat fatalities were observed during this survey period.

3.2.1 Array 1

Array 1 and its associated fence were surveyed three times during this reporting period: 26–30 August, 23–27 September, and 21–25 October. No fatalities were found during the first 5-day repeat search, but two were found during the week of 23 September (Table 3): a partial wing and feather spot of a house finch (*Carpodacus mexicanus*) were found, and the feather spot of a mourning dove was found. Both of these feather spots persisted until the fifth day of the survey, when they were collected. Both of these fatalities were likely overlooked by weekly searchers. During the week of 21 October, a common raven (*Corvus corax*) feather spot was found. This feather spot also persisted to day 5 of the survey interval, when it was collected by repeat searchers.

The carcass of a horned lark was found on 23 October 2013 on private land on the opposite side of the searched fenceline. The horned lark was partially lodged in the branches of a tumbleweed, and a small feather spot was present around the carcass. The carcass was gone the next day, but the feather spot persisted through the 5-day search interval. The camera trap failed to capture an image of the scavenger.

3.2.2 Array 2 North and South

Array 2 North and South was also searched three times during this reporting period. During the week of 2 September, two fatalities were found. On 2 September, two horned lark feather spots were found in Array 2 South. During the second survey, the week of 30 September, three fatalities were found in Array 2 North. On 1 October, the feather spots of a horned lark and a mourning dove were both found, and both feather spots persisted until the fifth day of the survey. Both of these feather spots were likely overlooked by weekly searchers. On 2 October, the carcass of a horned lark was found. It was removed on 3 October by fatality searchers. During the final search period, the feather spot of a mourning dove was found on 1 November in Array 2 South. Because this was the final day of the 5-day survey, the feather spot was collected immediately.

3.2.3 Array 2 Serengeti

Array 2 Serengeti was searched three times during this reporting period. During the weeks of 23 September and 21 November, nothing was found. On 26 August, the feather spot of a mourning dove was found. Because it was found on the first day of the survey, it was collected immediately.

3.2.4 Array 4

Array 4 was searched four times during this reporting period. During the weeks of 19 August and 16 September, nothing was found. In the week of 14 October, the feather spot of a common raven was found. This feather spot persisted for the remainder of the 5-day search interval and was collected on the fifth day. On 14 November, the feather spot of a western meadowlark (*Sturnella neglecta*) was found. Some feathers were found on top of the solar panels, indicating a panel strike and/or avian scavenging. This feather spot was collected on the following day, the fifth day of the survey.

3.2.5 Array 5

Array 5 was also searched four times during this reporting period. During the weeks of 16 September and 14 October , no fatalities were found. On 21 August, a lark sparrow (*Chondestes grammacus*) was found in the array. This fatality persisted to the fifth day of the survey, when it was collected. On 11 November, the large feather spot of a house finch was found. Because it was found on the first day of the survey, it was collected immediately.

3.2.6 Array 6

Five-day repeats in Array 6 began for the first time on 4 November 2013. Therefore, only one survey was conducted during this period, and the feather spot of a rock pigeon was found on the fifth day of the survey, on 8 November 2013.

3.2.7 Array 8

Array 8 was surveyed four times during this reporting period, and three fatalities were found in the array, and two fatalities were found along the fence line. On 21 August, the feather spot of a horned lark was found, and on 22 August, the feather spot of a long-eared owl (*Asio otus*) was found. Both feather spots persisted until the fifth day of the survey, when they were collected. On 11 November 2013, the feather spot of a western meadowlark was found in the array. Because it was found on the first day of the survey, it was collected immediately.

On the 14 October, the feather spot of a mourning dove was found along the fence. On 11 November, the feather spot of a mourning dove was found along the fence. Because both of these feather spots were found on the first day of the 5-day survey, they were collected immediately.

3.2.8 MVOH Line

The MVOH Line was surveyed three times during this reporting period, and two fatalities were found. No fatalities were found during the weeks of 4 November or 9 September. On 7 October, two feather spots were found. Both feather spots were from western meadowlarks. Because they were found on the first day of the survey, they were collected immediately.

3.3 1-Day Repeat Surveys

3.3.1 Weekly Search Areas

During the 1-day repeat surveys of regular weekly search areas, conducted between 16 August and 15 November 2013, six avian fatalities were observed in the surveyed operational portions of the Project site (Table 4, at the end of this section). No bat fatalities were observed during this period. All fatalities were found in the 1-day repeat survey areas of Array 1, Array 2 North and South, Array 7, Array 8, and the Gen-tie Line; no fatalities were found in the 1-day repeat survey areas of any fencelines, control plots, or Array 2 Serengeti, Array 4, Array 5, Array 9, Array 11, or the MVOH Line.

3.3.1.1 Array 1

One avian fatality was found in Array 1 during this reporting period. On 18 October, the feather spot of a horned lark was found. This feather spot was judged to be older than 24 hours, and therefore was likely missed by weekly searchers.

3.3.1.2 Array 2 North and South

Two avian fatalities were found in Array 2 during this period. One, the feather spot of a mourning dove, was found on 11 September. The other, the feather spot of a horned lark, was found on 9 October, and likely was missed by weekly searchers.

3.3.1.3 Array 7

A partial wing and feather spot of a mourning dove were found together in Array 7 on 8 November 2013.

3.3.1.4 Array 8

The feather spot of a mourning dove was found on 17 September. It was likely missed by weekly searchers.

3.3.1.5 Gen-Tie Line

The feathers and partial wing of a house finch was found on 24 October 2013. Several feathers were ground into the dirt; therefore, the feather spot was judged to be older than a day, and was likely missed by regular searchers.

3.3.2 5-day Repeat Survey Areas

During the 1-day repeat surveys of 5-day search areas, conducted between 16 August and 15 November 2013, no bat fatalities were observed in the surveyed operational portions of the Project site, and only two avian fatalities were found (Table 5, at the end of this section). One fatality, the feather spot of a mourning dove, was found along the Array 8 fence on 18 October.

The second, the feather spot of a common raven, was found on in Array 9 on 8 November. Some feathers were sheared at the bottom, indicating a mammalian scavenger species. Both of these fatalities were missed by 5-day repeat searchers.

Table 3. Results of 5-Day Repeat Surveys Conducted between 16 August and 15 November 2013

Location	Survey Period	Date Fatality Detected	Number of Days that Fatality Persisted	Species	UTM Zone	Easting	Northing	Observation Details

Section 4.0 Discussion

4.1 Weekly Fatality Searches

Given that the majority (approximately 80%, or 83 of 103) of the post-construction avian fatalities found during this quarter were feather spots, definitive causes of death were difficult to determine. Feather spots may indicate collision with a solar panel or a powerline, but in the absence of evidence of bodily injuries, it is impossible to determine the direct cause of death. For example, feather spots can indicate nonlethal panel strikes, with fatalities occurring when predators take advantage of a stunned bird. In this situation, although the cause of death is only indirectly related to the presence of the panels, it would be still be classified as being caused by a collision. Feather spots may also indicate that a lethal panel collision or powerline collision occurred, and that the body was later scavenged. Alternatively, feather spots may simply indicate direct mammalian or avian predation. Because no direct observations of predation or collisions were made during this period, causes of death could not be determined.

Mourning doves represented the highest number of fatalities in the arrays. This pattern corresponds with the mourning dove roosting activity often observed by fatality searchers during this quarter. Small flocks of mourning doves were frequently seen roosting under the solar panels, and when flushed, birds were observed quickly navigating through the panels. Mourning doves are well known as fast fliers, capable of sudden changes in altitude (Goodwin 1983). It is possible that, when fleeing in this highly cluttered environment, some birds may collide with the panels. Alternatively, the relatively higher numbers of fatalities for mourning doves may correspond to a high density of the species in the arrays. Mourning doves appear to favor the arrays for resting, as evidenced not only by their presence, but by their abundant sign (roosting and preening sites with abundant fecal droppings) in the arrays. Their prevalence may offer greater opportunities for avian and mammalian predators to prey on these birds. Most likely, the higher incidence of mourning dove fatalities is a combination of both factors.

Horned larks represented the second most frequently detected species of fatality. However, horned lark fatalities were much more numerous during the previous quarter. Large flocks were observed in surrounding Conservation Lands and around the Evaporation Pond. Although horned lark abundance on the Project site still appears to be high, they may be spending less time in the arrays, which could explain the change from the previous quarter.

Because surveys of the control plots detected background avian mortality, a corresponding percentage of the total fatalities found in each of the arrays was likely attributable to natural causes unrelated to the solar panels and other Project infrastructure. In the annual fatality report for 2014, the fatality estimate for the Project will be adjusted accordingly to reflect this background mortality.

Although assessing cause of death from feather spots is difficult, all feather spots found along the Gen-tie and MVOH Lines were located directly, or nearly directly, under these lines. This result suggests that all of these fatalities were caused by powerline collisions and that the remains found were indicative of scavenging, rather than predation. In all cases, whole carcasses found under the Gen-tie and MVOH Lines showed no signs of injury or illness. These individuals may have sustained internal injuries that were not visible. It is possible that predation by resident predators also contributed to some of these fatalities; however, study of a linear control would be necessary (allowing collection of background fatality information for a linear feature) to understand whether the observed rates and types of mortality are unique to the distribution lines or random.

Searchers continued to detect more fatalities along the Gen-tie Line than along the MVOH Line, as in previous quarters. Additionally, more migratory species (e.g., yellow-rumped warbler [*Dendroica coronata*] and savannah sparrow) were detected along the Gen-tie Line than along the MVOH Line or in any of the other Project elements. Many migratory species fly at night or in early morning hours (Bevanger 1994), and this behavior may increase their susceptibility to powerline collisions. Also, many of the Gen-tie Line fatalities were found in or near the tamarisk pond (*Tamarisk* spp.), which is located directly underneath the Gen-tie Line between Gen-tie Line Towers #17 and #18. This area provides habitat for nesting birds and is likely an attractive stopover for migratory birds. Therefore, it is possible that birds are at greater risk of powerline collisions because they are attracted in larger numbers to this area. Furthermore, since beginning fatality surveys in the pond, many old (preconstruction) feather spots have been detected in this area. So the pond is likely known to be regular source of prey by resident predators, and this may also contribute to the high number of fatalities in this area.

Consistent with the previous quarter, total fatalities were higher in the whole of Array 2 compared to Array 1 (both surveyed at 100%). The whole of Array 2 is almost twice as large as Array 1, so size is a likely factor in the differences of total fatalities. However, it is also possible that the Gen-tie Line, which is located directly east of and closest to Array 2, could be a source of avian carcasses for resident scavengers. In other words, Array 2 may provide a protected area where scavengers may consume carcasses found near the line. No fatalities were found in Array 5, which may be an effect of the small size of this array and the number of trackers (four) searched. Fatality rates in Arrays 4 and 8 (surveyed at 20%) were low compared with one another. Fatality rates in Arrays 6 and 7 were low, and no fatalities were found in Arrays 9 or 11, their associated fences or controls plots, or the Evaporation Pond. However, surveys of Arrays 6, 7, 9, and 11, and of the Evaporation Pond, did not begin until the middle or latter part of the reporting period. Therefore, it is too early to make any qualitative or quantitative inferences about these sites.

4.2 Repeat Surveys

Because of issues cited in the previous quarterly report, the protocol for 5-day and regular weekly searchers working in overlapping areas changed at the beginning of June 2013. Therefore, in this quarter, it was possible to determine the permanence of all feather spots and carcasses, whether or not they were detected during regular weekly searches. Although this quarter offered a relatively small sample size (N=22), the data suggest that the relative permanence of feather spots is much greater than that of carcasses. This finding is supported by the overall proportion of carcasses to feather spots found in the arrays.

A general assumption of fatality searches is that searchers are not 100% efficient at finding carcasses, because of both environmental and individual constraints (e.g., vegetation height, visual obstacles such as support poles for the arrays, and observer fatigue). The results of both the 1-day and the 5-day repeat surveys support this assumption: more than half of the finds in repeat searches were missed during the regular weekly searches. Although the number of fatalities found by weekly searchers but missed by repeat searchers was not examined, there are recorded cases of weekly searchers finding fatalities that repeat searchers did not find, so it is likely that searcher misses go in both directions. Also, the low rates of consistency between the findings of regular weekly searchers and those of repeat searchers suggest that search outcomes may be affected by both random differences and differences that vary by individual searcher. For example, a taller searcher will have a reduced field of vision into adjacent rows compared to a shorter searcher. This variation is unlikely to be fully compensated for, even through conscious efforts to look under the panels. Likewise, there are tradeoffs based on where searchers focus their field of vision: if a searcher focuses on tufts of tall grass on the sides of array rows, he or she may overlook fatalities directly underfoot, and vice versa.

In the context of the year, 5-day repeat searches serve to provide an independent estimate of fatalities that occur on site. Also, the ongoing nature of these surveys allows estimation of deposition rates over the year and during each season. The limited scope of this quarterly report does not allow for in-depth analysis of these rates, but both will be addressed in the annual report.

9/26/2013	MODO	Array 1	11S	233708	3915565	Feather spot: 100+ body feathers and 16+ flight feathers (primaries, secondaries, and retrices).
11/7/2013	MODO	Array 1	11S	233870	3915505	Feather spot: one wing and 20 body feathers.
10/10/2013	SAVS	Array 1	11S	233921	3915612	Feather spot: 10 flight and 75 body feathers (breast, coverts).
10/10/2013	SAVS	Array 1	11S	234040	3915699	Feather spot: 150 body feathers (belly, breast, and mantle coverts) and 20 flight feathers (primary, secondary, and tail).
10/17/2013	SOSP	Array 1	11S	233935	3915659	Feather spot: three wing and 75 contour feathers.
10/29/2013	ROPI	Array 1–2 Fence	11S	234527	3914904	Feather spot: 20 contour feathers.
11/5/2013	MODO	Array 2 control	11S	234298	3913537	Partial specimen: wing and feathers, bone, and heart. Twenty primaries and secondaries, one wing, ten tail, and 100+ body feathers.
11/12/2013	MODO	Array 2 control	11S	233665	3914133	Feather spot: 20 body feathers.
10/8/2013	AMPI	Array 2 North	11S	233825	3915053	Feather Spot: eight primary feathers in two clumps.
9/24/2013	BUOW	Array 2 North	11S	233969	3915190	Feather spot: breast feathers.
10/15/2013	EUST	Array 2 North	11S	234023	3914990	Feather spot: five to eight tail feathers, five to ten wing feathers, and 50+ contour feathers.
11/12/2013	HOFI	Array 2 North	11S	234201	3915219	Feather spot: 200–300 body feathers and three or four wing feathers.

Species Codes

AMKE- American kestrel
AMPI – American pipit
BNOW – Barn owl
BRBL – Brewer's blackbird
BUOW – Burrowing owl
CORA - Common raven
EUST – European starling
HOFI – House finch
HOLA – Horned lark
LOSH – Loggerhead shrike
MODO – Mourning dove
OCWA/WIWA – Orange-crowned or Wilson's warbler
RCKI – Ruby-crowned kinglet
ROPI – Rock pigeon
SAVS – Savannah sparrow
SOSP – Song sparrow
SPTO – Spotted towhee
WEME – Western meadowlark
YRWA – Yellow-rumped warbler

Survey Date	ALPHA Code	Site	UTM Zone	Easting	Northing	Observation Details
11/12/2013	HOFI	Array 2 North	11S	234311	3915321	Feather spot: five primaries attached together with very dried skin.
8/27/2013	HOLA	Array 2 North	11S	234323	3915324	Partial specimen: right wing with exposed bone and dried muscle tendons/ligaments.
9/3/2013	HOLA	Array 2 North	11S	234323	3915312	Feather spot: five tail feathers, five primaries, three secondaries, and 100+ body feathers.
9/10/2013	HOLA	Array 2 North	11S	234492	3915098	Partial specimen: two wings, five tail feathers, and 30+ body feathers.
10/15/2013	HOLA	Array 2 North	11S	233828	3915049	Feather spot: two secondaries and a few coverts.
8/27/2013	MODO	Array 2 North	11S	234310	3915241	Feather spot: seven tail feathers, 30 body feathers, and one primary.
9/24/2013	MODO	Array 2 North	11S	234156	3914993	Feather spot: five clumped body feathers; ten body feathers total. Two clumps of feathers as though plucked, one feather in sheath (not molted).
10/22/2013	MODO	Array 2 North	11S	234262	3915238	Feather spot: 20 contour feathers.
10/22/2013	MODO	Array 2 North	11S	234149	3915041	Feather spot: two wing feathers (secondaries).
9/24/2013	ROPI	Array 2 North	11S	234156	3915037	Feather spot: five secondary feathers and one clump of five body feathers.
10/15/2013	SAVS	Array 2 North	11S	234251	3915140	Partial specimen: partial wing (ten primary and secondary feathers), plus three tail feathers, five wing coverts, and 15 breast feathers.
10/29/2013	Unknown	Array 2 North	11S	233790	3915105	Partial specimen: pelvic bone.

About Argonne National Laboratory
Argonne is a U.S. Department of Energy laboratory managed by UChicago Argonne, LLC under contract DE-AC02-06CH11357. The Laboratory's main facility is outside Chicago, at 9700 South Cass Avenue, Argonne, Illinois 60439. For information about Argonne and its pioneering science and technology programs, see www.anl.gov.

DOCUMENT AVAILABILITY

Online Access: U.S. Department of Energy (DOE) reports produced after 1991 and a growing number of pre-1991 documents are available free via DOE's SciTech Connect (http://www.osti.gov/scitech/).

Reports not in digital format may be purchased by the public from the National Technical Information Service (NTIS):

U.S. Department of Commerce
National Technical Information Service
5301 Shawnee Road
Alexandria, VA 22312

April 2015

Bibliography of Literature for Avian Issues in Solar and Wind Energy and Other Activities

Utility-scale solar energy has been a rapidly expanding energy sector in the United States in recent years and is expected to continue to grow. In 2014, concerns were raised over the risk of avian fatalities associated with utility-scale solar plants. With funding from the U.S. Department of Energy SunShot Program, Argonne National Laboratory and the National Renewable Energy Laboratory studied the issue and released *A Review of Avian Monitoring and Mitigation Information at Existing Utility-Scale Solar Facilities* (ANL/EVS-15/2, March 2015). A comprehensive literature review included peer-reviewed journal articles on avian fatalities from solar energy facilities and other sources (e.g., wind energy, building collisions, etc.), project-specific technical reports on avian monitoring and fatality at solar facilities, information on mitigation measures and best management practices, and literature pertaining to avian behavioral patterns and habitat use. The source citations are listed in this bibliography; they are current through December 2014.

The publications are organized by topic. Those with broader applicability are listed under more than one. The topics include:

1. Avian Monitoring and Fatality at Solar Energy Facilities
2. Solar Energy Project-Specific References
3. Avian Monitoring and Fatality at Wind Energy Facilities
4. Avian Fatality from Sources Other Than Solar and Wind Energy Development

AVIAN MORTALITY AT A SOLAR ENERGY POWER PLANT

By Michael D. McCrary, Robert L. McKernan,
Ralph W. Schreiber, William D. Wagner,
and Terry C. Sciarrotta

In 1979, the United States Department of Energy, in conjunction with the Southern California Edison Company (SCE) and the Los Angeles Department of Water and Power, initiated the construction of Solar One, the world's largest solar energy power plant (Fig. 1). Until the construction of Solar One, the use of the sun's energy to produce electrical power had not been attempted on this scale, and the environmental hazards of operation of a solar power plant were unknown. In this paper we report on bird mortality at Solar One.

STUDY AREA AND METHODS

Solar One is a 10 megawatt, central receiver solar power plant consisting of a 32-ha field of 1818, 6.9 × 6.9 m mirrors (heliostats) which concentrate sunlight on a centrally located, tower-mounted boiler, 86 m in height (Fig. 1). The reflective surface area of each heliostat is approximately 40 m^2, and the total for all heliostats is approximately 72,500 m^2. When not directed at the tower during morning startup, testing, and maintenance, some or all of the heliostats are focused on standby points, four small areas (approximate diameter = 5 m) of sky around the tower at a height of 80 m. Temperatures within the standby points vary with the number of heliostats focused on them and the reflectivity of an object placed within them, but the temperature can be high enough to burn feathers and small insects.

Solar One is located in the Mojave Desert, 4 km east of Daggett, San Bernardino County, California (34°52′N, 116°51′W). The dominant desert plant community in this area is creosote bush (*Larrea divaricata*) scrub, although abandoned and active agricultural fields (alfalfa) and extensive (53 ha) evaporation ponds (Fig. 1) are adjacent to Solar One.

We visited Solar One approximately once per week (2–3 days per visit) on 6 occasions from 3 May through 8 June 1982 and on 34 occasions from 16 September 1982 through May 1983. During each visit 1–2 observers searched the facility for any evidence of bird mortality. Although searches were not conducted in a fixed pattern, the entire facility was covered during each visit. Bird carcasses were readily found because of the sparse vegetation and level ground of Solar One. Experiments involving the placement of 19 bird carcasses of various species within and just outside (<200 m) the fenced facility were conducted in May and September 1982 to measure the rate of bird carcass removal by scavengers. These carcasses were checked periodically until removed by scavengers or decomposed.

FIGURE 1. Aerial view of Solar One: (A) heliostat field, (B) central receiver tower, (C) evaporation ponds. Tower height = 86 m, diameter of field = 765 m.

To determine the impact of bird mortality on local populations, 1–2 observers conducted surveys of relative avian abundance within an area of approximately 150 ha surrounding Solar One, concentrating on the facility grounds (32 ha), evaporation ponds, and agricultural fields. These surveys were conducted on at least 2 d per visit for 3–4 h/d.

RESULTS

Solar One related animal mortality.—During approximately 40 wks of study, we documented 70 bird fatalities involving 26 species at Solar One (Table 1). The mean rate of mortality between visits was 1.7 birds ± 1.8 SD (n = 40, range 0–7). Results of the scavenger bias experiments indicate that from 10–30% of carcasses were removed between searches, thus, the actual rate of mortality may have been from 1.9–2.2 birds. Two causes of avian mortality were identified at Solar One, colliding with structures and burning from standby points.

The most frequent form of avian mortality was from collisions with Solar One structures. We documented 57 (81%) bird deaths (20 species) from collisions (Table 1). In most cases the cause of death was determined by the presence of broken bones (usually mandibles or wings) found through external examination. From the location of birds in relation to structures, most (>75%) died from colliding with the mirrored heliostats, although a dead Blue-winged Teal (*Anas discors*) with a broken wing was found on a platform of the receiver tower. On one occasion

TABLE 1. Avian mortality from burning and collisions at Solar One, 1982–1983.

Burn fatalities		Collision fatalities	
Species	Number of individuals	Species	Number of individuals
Vaux's Swift (*Chaetura vauxi*)	1	Eared Grebe (*Podiceps nigricollis*)	11
White-throated Swift (*Aeronautes saxatalis*)	2	Blue-winged Teal (*Anas discors*)	1
Hummingbird sp.	3	American Kestrel (*Falco sparverius*)	1
Cliff Swallow (*Hirundo pyrrhonota*)	2	American Coot (*Fulica americana*)	2

		Brewer's Blackbird (*Euphagas cyanocephalus*)	5
		House Finch (*Carpodacus mexicanus*)	4
Total	13	Total	57

in May 1982 a Solar One employee observed 4 Mourning Doves (*Zenaida macroura*) die in a collision with a single heliostat.

Thirteen (19%) birds (7 species) died from burning in the standby points (Table 1). Although we never observed a bird fly through one of the standby points, the heavily singed flight and contour feathers indicated that the birds burned to death (Fig. 2). Six (46%) of these fatalities involved aerial foragers (swifts and swallows) which are apparently more susceptible to this form of mortality because of their feeding behavior. Three of these aerial foragers died during a 2-wk period in May 1982, corresponding with the presence of the highest numbers of swifts and swallows observed (>500 per d), and an extensive period of heliostat testing when the occurrence and intensity of standby points was probably greater than at other times.

Relative avian abundance.—During 102 d from May–June 1982 (18 d) and September 1982–May 1983 (84 d), we recorded 107 bird species (daily mean = 16.7 ± 6.1 SD, n = 102) in the immediate area (150 ha) of Solar One. The mean daily count for individuals was 314 ± 203 SD (range 148–1040). Most avian species recorded at Solar One were migrants and only 15 species are year-round residents, with Horned Larks (*Eremophila alpestris*), European Starlings (*Sturnus vulgaris*), and House Finches (*Carpodacus mexicanus*) the most common breeding birds.

Of the habitats surveyed in this study, the evaporation ponds were the most heavily used by birds. Seventy percent of all species were recorded at least once at the ponds, and 45% were recorded only at the ponds; the majority of daily counts recorded mostly waterbirds.

DISCUSSION

Creosote bush scrub, which characterizes much of the undisturbed portions of the Mojave Desert near Solar One, is usually only sparsely inhabited by birds. The avian community of similar habitat in Arizona is usually less than 20 species (Tomoff, Ecology 55:396–403, 1974). However, we recorded 107 species in the vicinity of Solar One, 15 of which breed in the area. The special attraction of Solar One to birds is most likely related to the presence of a large, man-made water impoundment and irrigated agricultural fields, both of which produce an abundance of insects. Naturally occurring open water sources in the Mojave Desert are rare and usually ephemeral, while the man-made ponds near Solar One are permanent.

The most frequent form of avian mortality at Solar One during this study was from collisions with structures, primarily heliostats. Avian collisions are an inevitable by-product of almost all man-made structures (see Avery et al., FWS/OBS-80/54, 1980). Reflective surfaces are especially prone to collisions (Klem, Ph.D. thesis, Southern Illinois Univ., Carbondale, 1979), and it is not surprising that collisions with mirrored heliostats occur on a somewhat regular basis considering the reflective surface area of Solar One.

A form of avian mortality unique to solar central receiver power plants is burning in standby points. Death after being burned was infrequent in occurrence at Solar One, being in part a function of the frequent absence and variable intensity of standby points and the number of aerial foragers (swifts and swallows) in the airspace over Solar One.

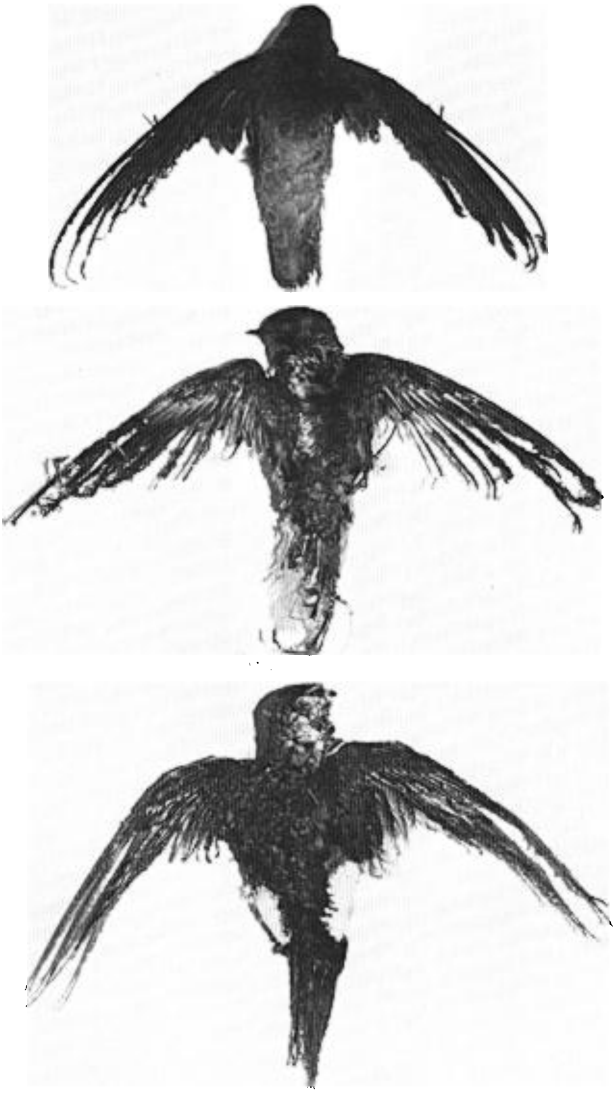

FIGURE 2. Three birds burned in standby points at Solar One. Top to bottom: Vaux's Swift (*Chaetura vauxi*), Barn Swallow (*Hirundo rustica*), and White-throated Swift (*Aeronautes saxatalis*). Note the heavily singed rectrices and remiges especially in the Barn Swallow.

Considering all known avian fatalities (70 birds) at Solar One during this study the impact of the facility on birds after construction appears minimal. Comparing the estimated rate of mortality (1.9–2.2 birds per wk) and mean relative avian abundance (314 birds per count) recorded in the vicinity of Solar One, only 0.6–0.7% of the local population present at any given time may have been affected during this study. The effect on the total population using the region in a year is obviously much less, but is unestimatable.

The results of this study suggest that, to reduce their impact on birds, future solar central receiver power plants in the Mojave Desert and other areas should not be sited in close proximity to open water or agricultural fields. The variety of species involved in avian mortality at Solar One indicates that caution should be taken when siting a solar power plant near populations of rare, threatened, or endangered species. If possible, the occurrence and intensity of standby points should be kept to a minimum. Since Solar One is only a 10 megawatt pilot facility, future projects designed to produce hundreds of megawatts will require several thousand heliostats and much taller receiver towers. The greater magnitude of these facilities may produce non-linear increases in the rate of avian mortality when compared to Solar One and extrapolations from this study should be made with caution. The removal of large tracts of desert from biological production for solar power generation and the ecological effects caused thereby should also be of concern.

SUMMARY

We studied avian mortality at an operating solar central receiver power plant in the Mojave Desert of southern California. During 40 wks of study we documented the deaths of 70 birds (26 species). The estimated mortality rate was 1.9–2.2 birds per week. Fifty-seven (81%) birds of 20 species died from collisions with Solar One structures, mainly the mirrored surfaces of heliostats. Thirteen (19%) birds (7 species) died from burns received by flying through standby points. The impact of this mortality on the local bird population is considered minimal (0.6–0.7% per wk).

ACKNOWLEDGMENTS

We thank J. Reeves (Research and Development, Southern California Edison Co.), P. Skvarna (SCE Site Manager of Solar One), D. Elliott (U.S. Department of Energy Project Director), and all other Solar One personnel for their valuable assistance on this project. P. Flanagan and G. Sawyer provided assistance in the field, and C. Barrows, P. Bloom, E. H. Burtt, Jr., J. Gore, and D. Klem provided editorial comments on the manuscript. This project was financially supported by a contract from the Southern California Edison Company to the Los Angeles County Museum of Natural History Foundation.

Post-construction Avian Mortality Monitoring Report for the Campo Verde Solar Project

First Quarter 2014

Prepared By:

Heritage Environmental Consultants, LLC

1 Introduction

The Campo Verde Solar Project is a solar photovoltaic (PV) energy generating facility (Solar Energy Facility) and an associated electrical transmission line (Gen-Tie Line) in southern Imperial County, California. The solar project is located on private lands and the gen-tie line is located on private and federal lands managed by the Bureau of Land Management (BLM). These are referred to collectively as the "Project."

A Bird and Bat Conservation Strategy (BBCS) was prepared that addresses activities potentially occurring during construction and operation of the Project (Heritage 2013). The BBCS was reviewed and approved by the U.S. Fish and Wildlife Service (FWS), California Department of Fish and Wildlife (CDFW), and BLM. The purpose of the Campo Verde BBCS was to develop and implement a program to identify and avoid risks to avian and bat species that could result from construction and operation of the Project. The goal of this BBCS was to implement a series of best practices, in order to construct and operate the Project to avoid or reduce risk to birds, bats and their habitats.

The post-construction avian mortality monitoring program was set up to comply with the methodology prescribed in the BBCS (Heritage 2013). The methodology is described in Section 6.1 of the BBCS and was approved by the FWS and CDFW. Quarterly reports documenting results of the monitoring program are required for the first year of program, and annually thereafter. Monitoring began in October 2013 just after completion of construction. This report is the second of four quarterly reports.

1.1 Project Description

The general location of the Project is approximately 7 miles southwest of the city of El Centro, Imperial County, California (**Figure 1**). The Project is south of I-8, west of Drew Road, and northeast and south of the Westside Main Canal. The Project consists of two component parts: (i) the Solar Energy Facility and (ii) an approximately 0.9-mile, 230-kilovolt (kV) aboveground, electrical gen-tie line and associated facilities that electrically connects the Solar Energy Facility on private land with the Imperial Valley Substation (IV Substation) located on federal land managed by the BLM.

The Solar Energy Facility is approximately 1,443 acres in size and uses First Solar PV modules that are generally non-reflective and convert sunlight into direct current (DC) electricity. The DC output of multiple rows of PV modules is collected through one or more combiner boxes and directed to an inverter that converts the DC electricity to alternating current (AC) electricity. From the inverter, the generated energy flows to a transformer where it is stepped up to distribution level voltage (approximately 34.5 kV). Multiple transformers are connected in parallel via 34.5 kV lines to the Project substation, where the power is stepped up to 230 kV. This substation is located at the southern end of the Solar Energy Facility near Liebert Road. The Gen-Tie Line connects the Project substation to the Imperial Valley Substation approximately 0.9 miles to the south.

The Gen-Tie Line uses double-circuit tubular steel monopole structures. Tower structure heights range from 100 to 135 feet. One side of the double-circuit structures currently supports three two- bundle conductors and one shield wire. Typical overall structure widths are approximately 20 feet.

Campo Verde Solar
Project Facilities

2 Methods

Monitoring of the Project was performed in order to document and report avian mortalities and identify areas of concern by tracking both the specific locations where mortalities occur as well as the extent of such mortalities. The monitoring program for the Project is based on the FWS guidance entitled "Monitoring Migratory Bird Take at Solar Power Facilities: An Experimental Approach" (FWS 2012) with modifications, and was approved by FWS.

2.1 Transect Sampling

Sampling transects were established for both the gen-tie line and solar field. For each kilometer of Gen-Tie Line, 300-meter transects were randomly established along the Gen-Tie Line allowing for approximately 30 percent of the Gen-Tie Line to be sampled. Transects were positioned along the centerline of the Gen-Tie Line. For the Campo Verde Solar Energy Facility, transects were also positioned to result in approximately 30-percent coverage of the site with no less than eight transects placed within the solar field itself. Transect selection was systematic randomized. The entire perimeter of the panel arrays was also surveyed during each survey period in addition to the interior transects.

Transects were surveyed for 7 consecutive days each month and each transect was surveyed once daily. Because of the large number of transects, sampling periods were 14-days; the first half of transects were walked for 7- day period and the second half for another 7 day period. One qualified observer walked along the pre-determined transects searching for bird/bat carcasses. When a carcass was observed, a GPS location was recorded at the carcass, the species was identified, the perpendicular distance from the transect to the carcass was measured, and information regarding carcass condition per FWS (2012) was recorded using paper datasheets. Once data were collected at a carcass, the observer returned to the pre-determined transect and continued with the survey.

The original protocol stated that each carcass would be marked uniquely and inconspicuously with tape and permanent marker to assess "recapture" rates. However, both the state scientific collection permit (SCP) and the federal special purpose utility permit (SPUT) enabling surveyors to handle carcasses were still being processed during this sampling period so no mark-recapture data was collected. Scavenger removal trials and searcher efficiency trials were also not performed due to the lack of handling permits. Therefore, all estimates presented in this report represent mortality estimates that are uncorrected for observer bias and scavenger removal rates. Future reports will address these biases, once permits are approved by the FWS and CDFW.

2.2 Analysis

Two primary analyses were proposed for mortality estimation. The first analysis used Program DISTANCE to determine the most effective transect width to search for carcasses. Distance models examined a variety of detection functions and used Aikake's Information Criterion (AIC)[1] for model selection. Most modeling used a 5% upper truncation to remove outliers. Specific model components are discussed in **Section 3.2**.

The second analysis would use Program MARK to estimate total number of mortalities controlling for detection rate, scavenging rate, and proximity to Project components. However, as described above, handling permits have not been approved by either the FWS or CDFW. Thus, mark-recapture protocols could not be implemented. Future reports will contain a mark-recapture analysis, pending approval of handling permits. Alternative analysis packages may be considered (as opposed to Program MARK); see **Section 4.4** for additional discussion of potential statistical analyses.

---

[1] AIC measures the relative quality of a given model by assessing both the model's complexity as well as the model goodness-of-fit to the observed data. Lower AIC values indicate higher quality models. Typically AIC values are compared among several possible models to select the "best" model or models.

Project mortality estimates rely on measuring a daily mortality rate that can be used as the basis for all mortality estimates. To calculate the corrected project mortality estimate, we did not count all mortalities observed during day 1 of the 7-day search period under the assumption that the those mortalities represent "bleed through" from the period prior to 24 hours preceding the first search. To accurately generate a rate, all mortalities used for this analysis need to have occurred within the 24 hours preceding discovery. Mortalities observed during the subsequent 6 days were then up-corrected to adjust for time not searched (since the search period captured 6 out of 28, 30 or 31 days each month), producing a time-corrected mortality estimate for each month.

Because taxonomic analyses do not use a rate, but are instead only concerned with the overall breakdown in mortalities, these analyses used all recorded mortality data, including those mortalities observed during day 1 of the 7-day search period. The use of these data from day one assumes that there is not persistence bias for different taxa of birds. Once scavenger removal trials are approved, this assumption can be tested and analyses will be adjusted if necessary.

3 Results

3.1 Overall Mortalities Observed

First quarter surveys for 2014 were conducted from January 11-24, 2014; February 8-21, 2014; and, March 8-21, 2014. A total of 17 avian mortalities were recorded. Seven (7) of these observed mortalities were recorded as "feather spots" (feather spots are defined as 10 or more feathers within a 1m^2 area suggestive of an avian mortality, see **Section 4.3**). **Table 1** provides a breakdown of mortalities by sampling period.

Table 1 – Observed Mortalities by Sampling Period

Mortality Type	January (1/11/14 – 1/24/14)	February (2/8/14 – 2/21/14)	March (3/8/14 – 3/21/14)	Q1 2014 TOTAL
Feather Spot Mortalities	6	1	0	7
Non-Feather Spot Mortalities	4	2	4	10
Total Mortalities	*10*	*3*	*4*	*17*

The inclusion of feather spots as observed mortalities is based on standard mortality monitoring protocols, which were largely developed for the wind energy industry. At wind energy facilities, the speed of the spinning blades can result in mortalities that leave very little detectible carcass behind, including only feather spots. Inclusion of feather spots as recorded mortalities at these facilities was intended to conservatively include mortalities caused by blade strikes that might otherwise go unrecorded. Potential bias resulting from the inclusion of feather spots in mortality data can arise from feather spots meeting the definition of a mortality but not actually resulting from an avian mortality. This bias can lead to overestimates of mortality rates. This bias is problematic in situations where feathers are commonly deposited in non-mortality related events but get included as incidents of avian morality (e.g. in and around common roost or perch sites, near active nests, etc.). Feather spots may also be caused by predation or attempted-predation events within a survey area. Based on the large proportion of feather spots observed during the Q4 2013 surveys (63%), observers used greater discretion when encountering feather spots to help mitigate this bias. Feather spots that strongly indicated a deposition of feathers that was unrelated to an avian mortality or injury were excluded from the database; in instances where observers were uncertain, the feathers spots were recorded as mortalities in order to be conservative. All of the following analyses present results that both include and exclude feather spots to present the full range of possible mortalities. Additional discussion regarding the use of feather spot data can be found in **Section 4.3**.

3.2 Effective Transect Width

DISTANCE analyses were performed using the data pooled across the three-month sampling period and **Table 2** presents the results of the DISTANCE analysis. It is important to note that none of the models fit the data well and model parameters were constrained to obtain monotonicity[2] in several cases. Additionally, sample sizes were very small during Q1 of 2014, further limiting the reliability of the DISTANCE analysis. Models were run using all observed mortalities, only non-feather spot mortalities, and excluding the north-south oriented perimeter transects (since the effective transect width is likely to

---

[2] DISTANCE analyses rely on the modeling of a detection function. This detection function models the change in probability of detecting a carcass as the distance from the transect increases. This type of modelling relies on the assumption that the detection function is monotonic. Monotonic means that the probability of detection *only* changes in one direction (decreases) with increasing distance from the transect. If the detection probability goes up and down as distance from the transect increases, then the results violate this assumption of monotonicity. Program DISTANCE automatically constrains certain model parameters to obtain monotonicity but the resulting model may have a poor fit to the observed data.

be significantly larger than for transects located in the interior of the solar arrays). However, sample sizes were too small to produce reliable model results for the non-feather spot dataset and the interior transects only dataset. Therefore, only the models run with the full dataset (with upper 5% truncation) are provided below.

The a priori[3] estimate of effective transect width was approximately 7.5 meters (this represents the width of two panel rows measured from the bottom of the panel immediately north of the designated transects to the bottom of the second panel to the south of the transect). Generally, the most likely models were consistent with that assumption. Sample sizes were small for all models run this quarter and model results should be used with a high degree of caution (e.g. note that modeled density was rounded to 0.00 for all model definitions indicating very low densities – i.e. low sample sizes).

Table 2 – Distance Analysis Results – includes feather spots

Model Definition	# of Parameters	AIC	ΔAIC	Density (mortalities per hectare)	95% CI	Effective Transect Width (m)
Hazard – Cosine*	3	112.55	0.00	0.00	0.00-0.00	14.27
Uniform – Cosine	0	112.94	0.39	0.00	0.00-0.00	34.10
Uniform – Polynomial	0	112.94	0.39	0.00	0.00-0.00	34.10
Half Normal – Polynomial	1	114.09	1.54	0.00	0.00-0.00	26.69
Half Normal – Hermit*	1	114.09	1.54	0.00	0.00-0.00	26.69

*Some parameters were constrained to obtain monotonicity.

3.3 Searcher Bias

As described above, permits allowing observers to handle bird carcasses were not in place during these surveys. As such, no searcher bias estimates were generated and overall mortality estimates were not adjusted to reflect searcher bias.

3.4 Scavenger Removal Bias

As described above, permits allowing observers to handle bird carcasses were not in place during these surveys. As such, no scavenger removal trials were completed and overall mortality estimates were not adjusted to reflect scavenger removal bias.

3.5 Corrected Project Mortality Estimate

Results from surveys conducted each month were used to generate discrete mortality estimates for each month surveyed. Monthly and overall project mortality estimates only used data from search days 2-7 (see **Section 2.2**). Monthly mortality estimates were used in order to detect seasonal variations in mortality rates. Also, data are presented to reflect estimates with and without feather spots, as discussed earlier. For the remainder of this section, mortality values are presented as "number of mortalities excluding feather spots"/"number of mortalities inclusive of feather spots".

While results of the DISTANCE analyses were less than conclusive, they were at least consistent with the a priori assumption of a minimum 7.5 meter effective transect width. Transect layout, in consideration of this assumed effective transect width, was designed to sample 30% of the overall PV array area. The time-corrected mortality estimates for each month were again up-corrected to account for the area not

---

[3] "A priori" hypotheses are those hypothesis developed based on a theoretical and logical understanding of the system in question and not based on empirical results. That is, a priori hypothesis are those generated before any results have been collected.

surveyed. Since no searcher efficiency or scavenger removal bias corrections were performed, this time- and area-corrected mortality estimate represents the overall monthly project mortality estimate. Mortality estimates were rounded to the nearest whole number. **Table 4** summarizes the corrected mortality estimates by month.

3.5.1 January Mortalities

A total of 1/5 mortalities were detected during days 2-7 of the January surveys. Correcting for time (the 6 day survey period represents approximately 19% of the total days in January) and area surveyed, the overall monthly project mortality estimate for January was 17/86.

3.5.2 February Mortalities

A total of 1/2 mortalities were detected during days 2-7 of the February surveys. Correcting for time (the 6 day survey period represents approximately 21% of the total days in February) and area surveyed, the overall monthly project mortality estimate for February was 16/31.

3.5.3 March Mortalities

A total of 1/1 mortalities were detected during days 2-7 of the March surveys. Correcting for time (the 6 day survey period represents approximately 19% of the total days in March) and area surveyed, the overall monthly project mortality estimate for March was 17/17.

3.5.4 First Quarter 2014 Corrected Mortality Estimates

After applying time and area corrections to the mortality counts for each month the overall project mortality estimate for the first quarter of 2014 is 50/134 birds.

Table 4 – Corrected Mortalities by Month

	January		February		March		Q1 Totals	
	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots
Raw Mortality Count (days 2-7)	1	5	1	2	1	1	3	8
Corrected Mortality Estimate	17	86	16	31	17	17	50	134

3.6 Taxonomic Composition of Observed Mortalities

The following analyses use all observed mortalities including those detected on search day 1 since the taxonomic composition is not a rate-dependent analysis (see **Section 2.2**).

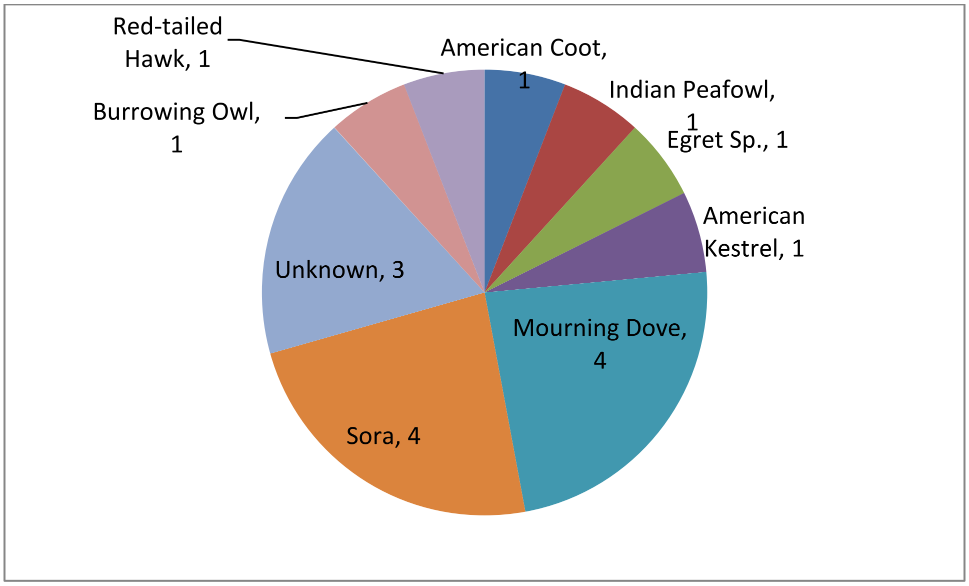
Table 5 – Raw Mortalities by Month (includes data from all search days)

	January		February		March		Q1 2014 Totals	
	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots
Raw Mortality Count (days 1-7)	4	10	2	3	4	4	10	17

3.6.1 Mortalities Including Feather Spots

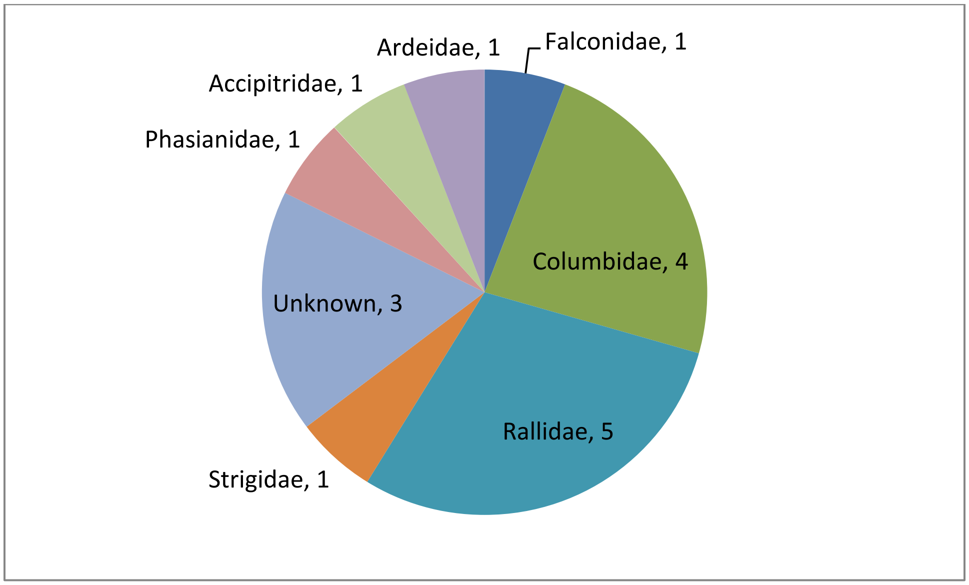
A total of 17 mortalities were observed when feather spots were included in the data set. Four (4) of these mortalities (24%) could not be identified to species. Of the 13 carcasses that could be identified to species, the most commonly observed species were Mourning Dove (*Zenaida macroura*; 4 mortalities; 31% of mortalities identified to species level) and Sora (*Porzana Carolina*; 4 mortalities; 31% of mortalities identified to species level). **Figure 2** presents the breakdown of observed mortalities by species.

Figure 2 – Mortalities by Species (includes feather spots)



Fourteen (14) of the 17 observed mortalities could be identified to the family level. Of these 14 mortalities, the families Rallidae (5 mortalities; 36% of mortalities identified to family level) and Columbidae (4 mortalities; 29% of mortalities identified to family level) were the most commonly observed mortalities. **Figure 3** presents the breakdown of observed mortalities by family.

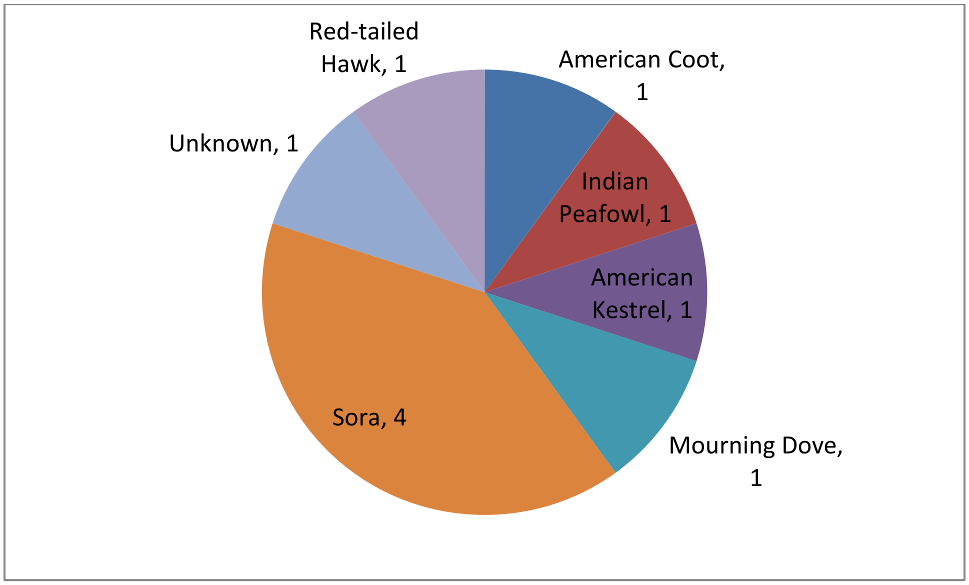
Figure 3 – Mortalities by Family (includes feather spots)



3.6.2 Mortalities Excluding Feather Spots

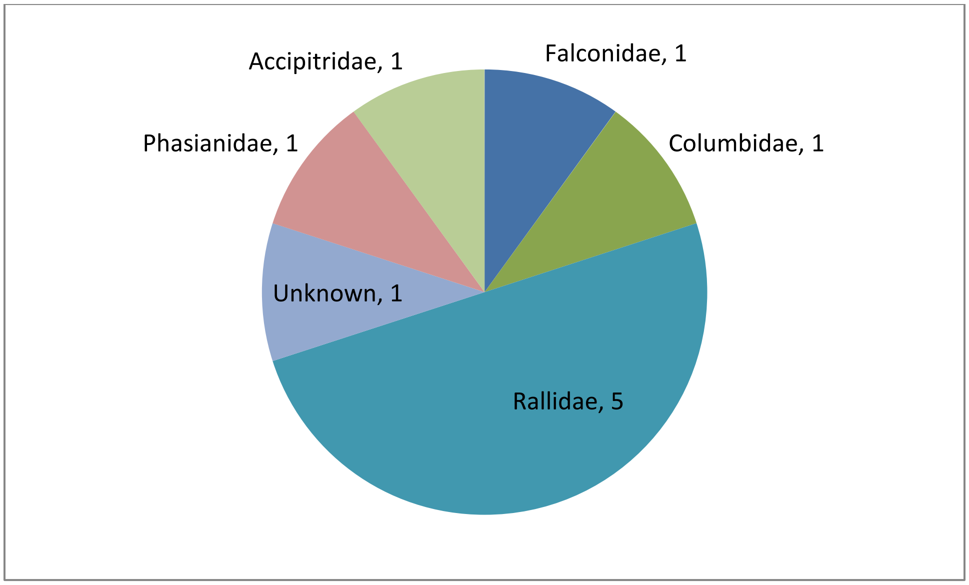
A total of 10 mortalities were observed when feather spots were excluded from the data set. One (1) of these mortalities (10%) could not be identified to species. Of the 9 carcasses that could be identified to species, the most commonly observed species Sora (4 mortalities; 44% of mortalities identified to species). **Figure 4** presents the breakdown of observed mortalities by species.

Figure 4 - Mortalities by Species (excludes feather spots)



Nine (9) of the 10 observed mortalities could be identified to the family level. Of these mortalities, the family Rallidae (5 mortalities; 56% of mortalities identified to family level) was the most commonly observed mortality. **Figure 5** presents the breakdown of observed mortalities by family.

Figure 5 – Mortalities by Family (excludes feather spots)



4 Discussion

4.1 Mortality Estimates

Searcher efficiency and scavenger removal trials can only result in up-correcting results (since searchers cannot detect >100% of carcasses and scavengers are unlikely to deposit carcasses within a survey area). Because searcher efficiency and scavenger removal trials were not performed during the first quarter surveys, the degree of underestimation is unknown. As soon as the Campo Verde Project receives a SPUT permit from FWS and a SCP from CDFW, searcher efficiency and scavenger removal trials will begin.

4.2 Seasonal Variations

When the estimated mortality rates included feather spot mortalities there was a strong variation month to month. January mortalities accounted for 64% of all mortalities, whereas February and March each accounted for 23% and 13%, respectively. When feather spots were excluded, however, mortality rates were relatively consistent month to month, only ranging between 31-34% each month.

4.3 Evaluation of Methodological Changes

The following changes to the methodology were implemented during the Q1 2013 surveys.

1. Direct Measurement of Perpendicular Distance – Per the FWS protocol (FWS 2012), during the Q4 2013 surveys and the January 2014 surveys a geographic information system (GIS) was used to measure the perpendicular distance a carcass was located from a transect line. Given the relatively small effective transect width (~7.5m) compared to typical GPS accuracy (~3m), we felt that this method was unlikely to be the most accurate. Beginning in February of 2014, we began directly measuring the perpendicular distance in the field using tape measures. The errors in GIS measurement are suspected to have contributed to the lack of monotonicity in the model results from the Q4 2013 surveys as well as the Q1 2014 surveys (especially since 64% of the Q1 2014 mortalities occurred in January). Sample sizes from February and March are far too small to produce a reliable DISTANCE model that could test if the direct measurements have improved model fit. This methodological change will continue to be examined in future reports.
2. Feather Spots – As described in **Section 3.1**, feather spots were problematic in that it is unclear if all feather spots can truly be attributed to an avian mortality. It is presumed that some proportion of observed feather spots were the result of avian mortality potentially attributable to project operations or infrastructure; but this proportion is unknown. During collection of data in the fourth quarter 2013, a strict definition of a feather spot mortality was used (≥10 feathers within a 1m^2 area). Beginning with the February surveys, we gave observers greater discretion in determining whether observed feathers should be recorded as a likely mortality. This likely resulted in the exclusion of some feather spots where only a few feathers were present with no other evidence of mortality (flesh associated with the feathers, large groups of remiges, feathers from a species not commonly observed in the panel arrays, large numbers of feathers in a concentrated area). With greater discretion, observers still recorded feather spot mortalities but excluded those cases that just barely met the minimum criteria but did not show any other evidence that an avian mortality had occurred. In cases of any uncertainty, observers recorded feather spots as mortalities in order to generate conservative estimates of mortality. During the February and March surveys feather spot mortalities represented a lower proportion of total mortalities (33% and 0% respectively) compared to the Q1 results (63%).

4.4 Recommended Methodological Changes

The following changes are recommended to improve survey efficiency and accuracy as well as to improve data collection and analysis.

1. Searcher Efficiency and Scavenger Removal Bias – The results presented in this report are uncorrected for searcher efficiency and scavenger removal. Searcher efficiency at this site is

likely very high (near 100%) given the level ground and almost entirely unvegetated environment. As such, the searcher efficiency bias is unlikely to have resulted in a significant underestimate of mortality. However, scavenger removal rates are unknown and could be a source of bias. Numerous potential avian and mammalian scavengers are known to occur in and around the project site. Until scavenger removal trials are performed, the magnitude of this source of bias is unknown. As soon as state and federal permits are approved, these trials will be initiated.

2. Alternative Statistical Analysis Packages – Since the publication of the project BBCS (Heritage 2013), a potentially more robust mortality estimation program has been released for use with the statistical analysis software Program R, called *facilityCMR*. This program offers several potential advantages over the Warren-Hicks Estimator including analyzing covariance between searcher efficiency and scavenger removal rates and allowing for analysis of carcass condition. We propose using the *facilityCMR* software in future analyses, as soon as searcher efficiency and scavenger removal trials are permitted. This would be used in lieu of the Warren-Hicks Estimator and Program MARK and better reflects current FWS guidance on mortality studies at solar facilities.

Post-construction Avian Mortality Monitoring Report for the Campo Verde Solar Project

Second Quarter 2014 (April, May, June)

Prepared By:

Heritage Environmental Consultants, LLC

1 Introduction

The Campo Verde Solar Project is a solar photovoltaic (PV) energy generating facility (Solar Energy Facility) and an associated electrical transmission line (Gen-Tie Line) in southern Imperial County, California. The solar project is located on private lands and the gen-tie line is located on private and federal lands managed by the Bureau of Land Management (BLM). These are referred to collectively as the "Project."

A Bird and Bat Conservation Strategy (BBCS) was prepared that addresses activities potentially occurring during construction and operation of the Project (Heritage 2013). The BBCS was reviewed and approved by the U.S. Fish and Wildlife Service (FWS), California Department of Fish and Wildlife (CDFW), and BLM. The purpose of the Campo Verde BBCS was to develop and implement a program to identify and avoid risks to avian and bat species that could result from construction and operation of the Project. The goal of this BBCS was to implement a series of best practices, in order to construct and operate the Project to avoid or reduce risk to birds, bats and their habitats.

The post-construction avian mortality monitoring program was set up to comply with the methodology prescribed in the BBCS (Heritage 2013). The methodology is described in Section 6.1 of the BBCS and was approved by the FWS and CDFW. Quarterly reports documenting results of the monitoring program are required for the first year of program, and annually thereafter. Monitoring began in October 2013 just after completion of construction. This report is the third of four quarterly reports for the first survey year.

1.1 Project Description

The general location of the Project is approximately 7 miles southwest of the city of El Centro, Imperial County, California (**Figure 1**). The Project is south of I-8, west of Drew Road, and northeast and south of the Westside Main Canal. The Project consists of two component parts: (i) the Solar Energy Facility and (ii) an approximately 0.9-mile, 230-kilovolt (kV) aboveground, electrical gen-tie line and associated facilities that electrically connects the Solar Energy Facility on private land with the Imperial Valley Substation (IV Substation) located on federal land managed by the BLM.

The Solar Energy Facility is approximately 1,443 acres in size and uses First Solar PV modules that are generally non-reflective and convert sunlight into direct current (DC) electricity. The DC output of multiple rows of PV modules is collected through one or more combiner boxes and directed to an inverter that converts the DC electricity to alternating current (AC) electricity. From the inverter, the generated energy flows to a transformer where it is stepped up to distribution level voltage (approximately 34.5 kV). Multiple transformers are connected in parallel via 34.5 kV lines to the Project substation, where the power is stepped up to 230 kV. This substation is located at the southern end of the Solar Energy Facility near Liebert Road. The Gen-Tie Line connects the Project substation to the Imperial Valley Substation approximately 0.9 miles to the south.

The Gen-Tie Line uses double-circuit tubular steel monopole structures. Tower structure heights range from 100 to 135 feet. One side of the double-circuit structures currently supports three two- bundle conductors and one shield wire. Typical overall structure widths are approximately 20 feet.

Project Facilities

2 Methods

Monitoring of the Project was performed in order to document and report avian mortalities and identify areas of concern by tracking both the specific locations where mortalities occur as well as the extent of such mortalities. The monitoring program for the Project is based on the FWS guidance entitled "Monitoring Migratory Bird Take at Solar Power Facilities: An Experimental Approach" (FWS 2012) with modifications, and was approved by FWS.

2.1 Transect Sampling

Sampling transects were established for both the gen-tie line and solar field. For each kilometer of Gen-Tie Line, 300-meter transects were randomly established along the Gen-Tie Line allowing for approximately 30 percent of the Gen-Tie Line to be sampled. Transects were positioned along the centerline of the Gen-Tie Line. For the Campo Verde Solar Energy Facility, transects were also positioned to result in approximately 30-percent coverage of the site with no less than eight transects placed within the solar field itself. Transect selection was systematic randomized. The entire perimeter of the panel arrays was also surveyed during each survey period in addition to the interior transects.

Transects were surveyed for 7 consecutive days each month and each transect was surveyed once daily. Because of the large number of transects, sampling periods were 14-days; the first half of transects were walked for 7- day period and the second half for another 7 day period. One qualified observer walked along the pre-determined transects searching for bird/bat carcasses. When a carcass was observed, a GPS location was recorded at the carcass, the species was identified, the perpendicular distance from the transect to the carcass was measured, and information regarding carcass condition per FWS (2012) was recorded using paper datasheets. Once data were collected at a carcass, the observer returned to the pre-determined transect and continued with the survey.

The original protocol stated that each carcass would be marked uniquely and inconspicuously with tape and permanent marker to assess "recapture" rates. However, both the state scientific collection permit (SCP) and the federal special purpose utility permit (SPUT) enabling surveyors to handle carcasses were still being processed during this sampling period so no mark-recapture data was collected. Scavenger removal trials and searcher efficiency trials were also not performed due to the lack of handling permits. Therefore, all estimates presented in this report represent mortality estimates that are uncorrected for observer bias and scavenger removal rates. Future reports will address these biases, once permits are approved by the FWS and CDFW.

2.2 Analysis

Two primary analyses were proposed for mortality estimation. The first analysis used Program DISTANCE to determine the most effective transect width to search for carcasses. Distance models examined a variety of detection functions and used Aikake's Information Criterion (AIC)[1] for model selection. Most modeling used a 5% upper truncation to remove outliers. Specific model components are discussed in **Section 3.2**.

The second analysis would use Program MARK to estimate total number of mortalities controlling for detection rate, scavenging rate, and proximity to Project components. However, as described above, handling permits have not been approved by either the FWS or CDFW. Thus, mark-recapture protocols could not be implemented. Future reports will contain a mark-recapture analysis, pending approval of handling permits. Alternative analysis packages may be considered (as opposed to Program MARK); see **Section 4.4** for additional discussion of potential statistical analyses.

---

[1] AIC measures the relative quality of a given model by assessing both the model's complexity as well as the model goodness-of-fit to the observed data. Lower AIC values indicate higher quality models. Typically AIC values are compared among several possible models to select the "best" model or models.

Project mortality estimates rely on measuring a daily mortality rate that can be used as the basis for all mortality estimates. To calculate the corrected project mortality estimate, we did not count all mortalities observed during day 1 of the 7-day search period under the assumption that the those mortalities represent "bleed through" from the period prior to 24 hours preceding the first search. To accurately generate a rate, all mortalities used for this analysis need to have occurred within the 24 hours preceding discovery. Mortalities observed during the subsequent 6 days were then up-corrected to adjust for time not searched (since the search period captured 6 out of 28, 30 or 31 days each month), producing a time-corrected mortality estimate for each month.

Because taxonomic analyses do not use a rate, but are instead only concerned with the overall breakdown in mortalities, these analyses used all recorded mortality data, including those mortalities observed during day 1 of the 7-day search period. The use of these data from day one assumes that there is not persistence bias for different taxa of birds. Once scavenger removal trials are approved, this assumption can be tested and analyses will be adjusted if necessary.

3 Results

3.1 Overall Mortalities Observed

Second quarter surveys for 2014 were conducted from April 14-27, 2014; May 9-22, 2014; and, June 14-27, 2014. A total of 10 avian mortalities were recorded. Three (3) of these observed mortalities were recorded as "feather spots". **Table 1** provides a breakdown of mortalities by sampling period.

Table 1 – Observed Mortalities by Sampling Period

Mortality Type	April (4/14/14 – 4/27/14)	May (5/9/14 – 5/22/14)	June (6/14/14 – 6/27/14)	Q2 2014 TOTAL
Feather Spot Mortalities	2	0	1	3
Non-Feather Spot Mortalities	2	1	4	7
Total Mortalities	*4*	*1*	*5*	*10*

The inclusion of feather spots as observed mortalities is based on standard mortality monitoring protocols, which were largely developed for the wind energy industry. At wind energy facilities, the speed of the spinning blades can result in mortalities that leave very little detectible carcass behind, including only feather spots. Inclusion of feather spots as recorded mortalities at these facilities was intended to conservatively include mortalities caused by blade strikes that might otherwise go unrecorded. Potential bias resulting from the inclusion of feather spots in mortality data can arise from feather spots meeting the definition of a mortality but not actually resulting from an avian mortality. This bias can lead to overestimates of mortality rates. This bias is problematic in situations where feathers are commonly deposited in non-mortality related events but get included as incidents of avian morality (e.g. in and around common roost or perch sites, near active nests, etc.). Feather spots may also be caused by predation or attempted-predation events within a survey area. Based on the large proportion of feather spots observed during the Q4 2013 and Q2 2014 surveys (63% and 41%, respectively), observers used greater discretion when encountering feather spots to help mitigate this bias. Feather spots that strongly indicated a deposition of feathers that was unrelated to an avian mortality or injury were excluded from the database; in instances where observers were uncertain, the feathers spots were recorded as mortalities in order to be conservative. All of the following analyses present results that both include and exclude feather spots to present the full range of possible mortalities.

3.2 Effective Transect Width

DISTANCE analyses were performed using the data pooled across the three-month sampling period and **Table 2** presents the results of the DISTANCE analysis. It is important to note that none of the models fit the data well and model parameters were constrained to obtain monotonicity[2] in several cases. Additionally, sample sizes were very small during Q2 of 2014, further limiting the reliability of the DISTANCE analysis. Models were run using all observed mortalities since sample sizes were far too small to run subdivided models.

---

[2] DISTANCE analyses rely on the modeling of a detection function. This detection function models the change in probability of detecting a carcass as the distance from the transect increases. This type of modelling relies on the assumption that the detection function is monotonic. Monotonic means that the probability of detection *only* changes in one direction (decreases) with increasing distance from the transect. If the detection probability goes up and down as distance from the transect increases, then the results violate this assumption of monotonicity. Program DISTANCE automatically constrains certain model parameters to obtain monotonicity but the resulting model may have a poor fit to the observed data.

The a priori[3] estimate of effective transect width was approximately 7.5 meters (this represents the width of two panel rows measured from the bottom of the panel immediately north of the designated transects to the bottom of the second panel to the south of the transect). Generally, the most likely models were consistent with or exceeded that assumption. Sample sizes were small for all models run this quarter and model results should be used with a high degree of caution (e.g. note that modeled density was rounded to 0.00 for all model definitions indicating very low densities – i.e. low sample sizes).

Table 2 – Distance Analysis Results – includes feather spots

Model Definition	# of Parameters	AIC	ΔAIC	Density (mortalities per hectare)	95% CI	Effective Transect Width (m)
Hazard – Cosine*	2	70.16	0.00	0.00	0.00-0.00	8.45
Uniform – Cosine*	3	75.93	5.76	0.00	0.00-0.00	20.55
Uniform – Polynomial*	4	78.49	8.33	0.00	0.00-0.00	22.05
Half Normal – Polynomial	1	79.08	8.92	0.00	0.00-0.00	29.19
Half Normal – Hermite	1	79.08	8.92	0.00	0.00-0.00	29.19

*Some parameters were constrained to obtain monotonicity.

3.3 Searcher Bias

As described above, permits allowing observers to handle bird carcasses had not been issued at the time of these surveys. As such, no searcher bias estimates were generated and overall mortality estimates were not adjusted to reflect searcher bias.

3.4 Scavenger Removal Bias

As described above, permits allowing observers to handle bird carcasses had not been issued at the time of these surveys. As such, no scavenger removal trials were completed and overall mortality estimates were not adjusted to reflect scavenger removal bias.

3.5 Corrected Project Mortality Estimate

Results from surveys conducted each month were used to generate discrete mortality estimates for each month surveyed. Monthly and overall project mortality estimates only used data from search days 2-7 (see **Section 2.2**). Monthly mortality estimates were used in order to detect seasonal variations in mortality rates. Also, data are presented to reflect estimates with and without feather spots, as discussed earlier. For the remainder of this section, mortality values are presented as "number of mortalities excluding feather spots"/"number of mortalities inclusive of feather spots".

While results of the DISTANCE analyses were less than conclusive, they were at least consistent with the a priori assumption of a minimum 7.5-meter effective transect width. Past quarterly DISTANCE analyses for this study have also supported the validity of the 7.5-meter transect. Transect layout, in consideration of this assumed effective transect width, was designed to sample 30% of the overall PV array area. The time-corrected mortality estimates for each month were again up-corrected to account for the area not surveyed. Since no searcher efficiency or scavenger removal bias corrections were performed, this time- and area-corrected mortality estimate represents the overall monthly project mortality estimate. Mortality

---

[3] "A priori" hypotheses are those hypothesis developed based on a theoretical and logical understanding of the system in question and not based on empirical results. That is, a priori hypothesis are those generated before any results have been collected.

estimates were rounded to the nearest whole number. **Table 4** summarizes the corrected mortality estimates by month.

3.5.1 April Mortalities

A total of 1/3 mortalities were detected during days 2-7 of the April surveys. Correcting for time (the 6 day survey period represents approximately 20% of the total days in April) and area surveyed, the overall monthly project mortality estimate for April was 17/50.

3.5.2 May Mortalities

A total of 1/1 mortalities were detected during days 2-7 of the May surveys. Correcting for time (the 6 day survey period represents approximately 19% of the total days in May) and area surveyed, the overall monthly project mortality estimate for May was 17/17.

3.5.3 June Mortalities

A total of 3/3 mortalities were detected during days 2-7 of the June surveys. Correcting for time (the 6 day survey period represents approximately 20% of the total days in June) and area surveyed, the overall monthly project mortality estimate for June was 50/50.

3.5.4 Second Quarter 2014 Corrected Mortality Estimates

After applying time and area corrections to the mortality counts for each month the overall project mortality estimate for the second quarter of 2014 is 84/117 birds.

Table 4 – Corrected Mortalities by Month

	April		May		June		Q2 Totals	
	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots
Raw Mortality Count (days 2-7)	1	3	1	1	3	3	5	7
Corrected Mortality Estimate	17	50	17	17	50	50	84	117

3.6 Taxonomic Composition of Observed Mortalities

The following analyses use all observed mortalities including those detected on search day 1 since the taxonomic composition is not a rate-dependent analysis (see **Section 2.2**).

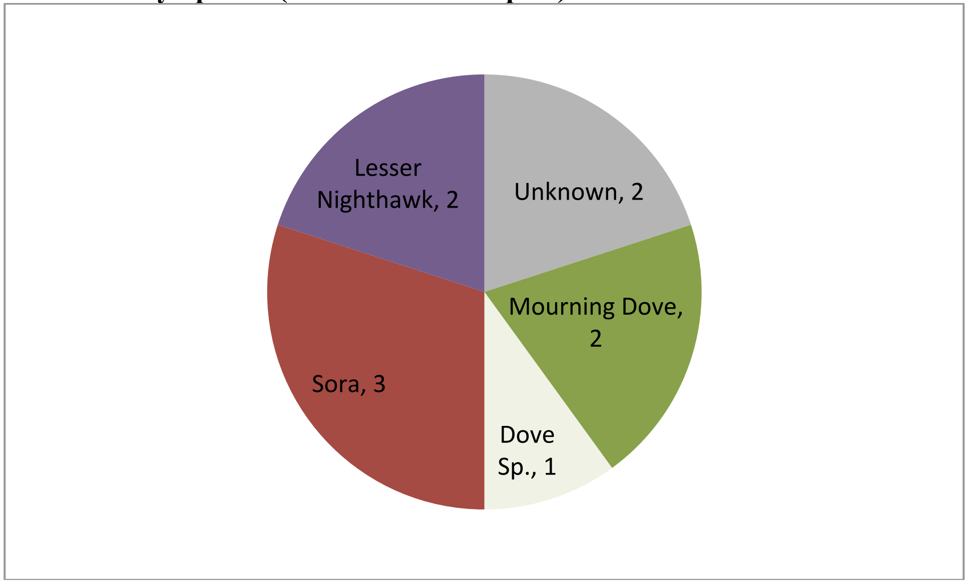
Table 5 – Raw Mortalities by Month (includes data from all search days)

	April		May		June		Q2 Totals	
	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots
Raw Mortality Count (days 1-7)	2	4	1	1	4	5	7	10

3.6.1 Mortalities Including Feather Spots

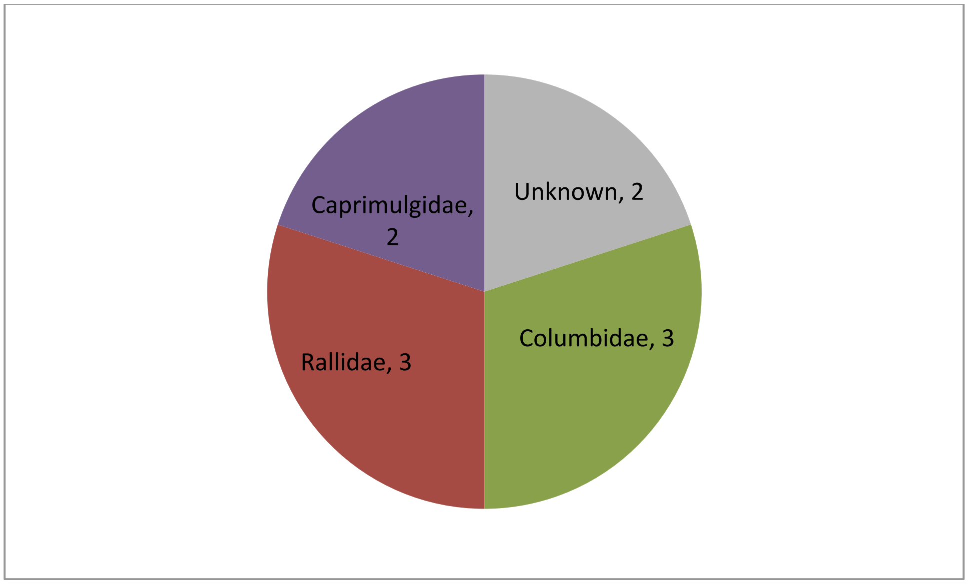
A total of 10 mortalities were observed when feather spots were included in the data set. Two (2) of these mortalities (20%) could not be identified to species. Of the 8 carcasses that could be identified to species, the most commonly observed species were Sora (*Porzana Carolina*; 3 mortalities; 37.5% of mortalities identified to species level), Mourning Dove (*Zenaida macroura*; 2 mortalities; 25% of mortalities identified to species level), and Lesser Nighthawk (*Chordeiles acutipennis*; 2 mortalities; 25% of mortalities identified to species level). **Figure 2** presents the breakdown of observed mortalities by species.

Figure 2 – Mortalities by Species (includes feather spots)



Eight (8) of the 10 observed mortalities could be identified to the family level. Of these 8 mortalities, the families Rallidae (3 mortalities; 37.5% of mortalities identified to family level) and Columbidae (3 mortalities; 37.5% of mortalities identified to family level) were the most commonly observed mortalities. **Figure 3** presents the breakdown of observed mortalities by family.

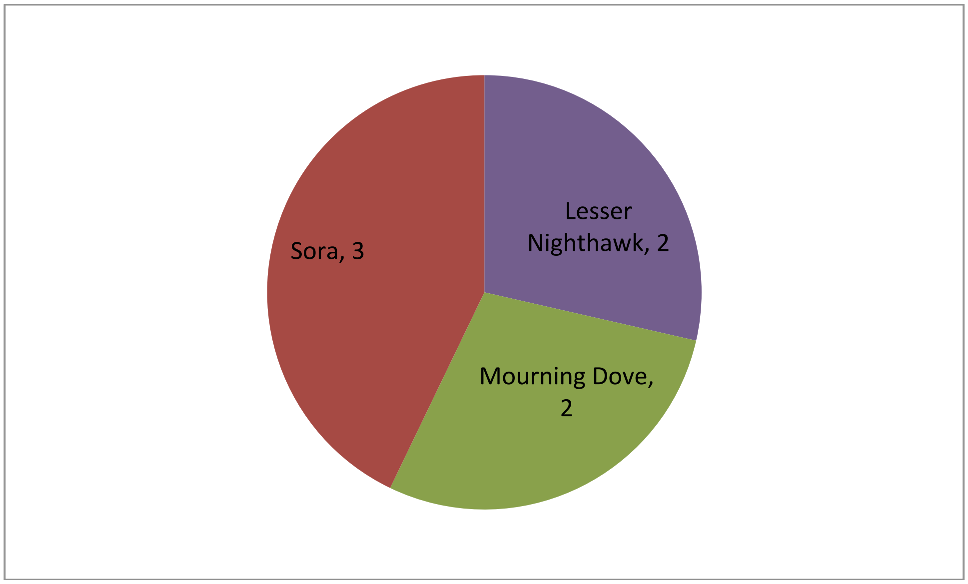
Figure 3 – Mortalities by Family (includes feather spots)



3.6.2 Mortalities Excluding Feather Spots

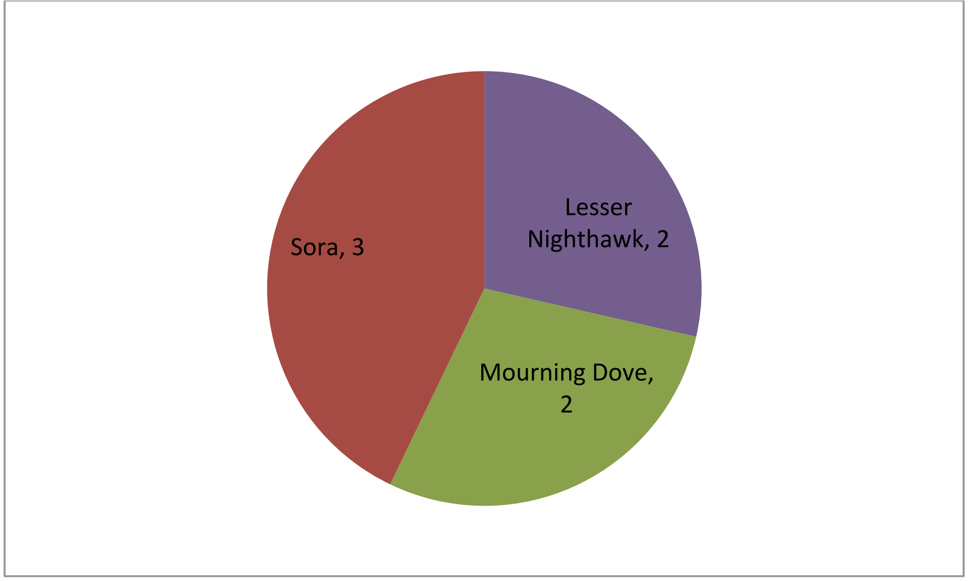
A total of 7 mortalities were observed when feather spots were excluded from the data set. All 7 of these mortalities (100%) could be identified to species. Of these 7 carcasses, the most commonly observed species was Sora (3 mortalities; 42.9% of mortalities identified to species). **Figure 4** presents the breakdown of observed mortalities by species.

Figure 4 - Mortalities by Species (excludes feather spots)



All 7 of the observed mortalities could be identified to the family level. Of these mortalities, the family Rallidae (3 mortalities; 42.9% of mortalities identified to family level) was the most commonly observed mortality. **Figure 5** presents the breakdown of observed mortalities by family.

Figure 5 – Mortalities by Family (excludes feather spots)



4 Discussion

4.1 Mortality Estimates

Searcher efficiency and scavenger removal trials can only result in up-correcting results (since searchers cannot detect >100% of carcasses and scavengers are unlikely to deposit carcasses within a survey area). Because searcher efficiency and scavenger removal trials were not performed during the second quarter surveys, the degree of underestimation is unknown. As soon as the Campo Verde Project receives a SPUT permit from FWS and a SCP from CDFW, searcher efficiency and scavenger removal trials will begin.

4.2 Seasonal Variations

When the estimated mortality rates included feather spot mortalities there was strong variation month to month, than as been observed in past quarterly summaries. May mortalities only accounted for 15% of all mortalities, whereas April and June each accounted for 60% each. When feather spots were excluded, mortality rates were more consistent month to month, only ranging between 15-43% each month. It should be noted that the sample size of observed mortalities was very low this quarter, making these types of analyses difficult to achieve high confidence levels.

4.3 Recommended Methodological Changes

The following changes are recommended to improve survey efficiency and accuracy as well as to improve data collection and analysis.

1. Searcher Efficiency and Scavenger Removal Bias – The results presented in this report are uncorrected for searcher efficiency and scavenger removal. Searcher efficiency at this site is likely very high (near 100%) given the level ground and almost entirely unvegetated environment. As such, the searcher efficiency bias is unlikely to have resulted in a significant underestimate of mortality. However, scavenger removal rates are unknown and could be a source of bias. Numerous potential avian and mammalian scavengers are known to occur in and around the project site. Until scavenger removal trials are performed, the magnitude of this source of bias is unknown. As soon as state and federal permits are approved, these trials will be initiated.
2. Alternative Statistical Analysis Packages – Since the publication of the project BBCS (Heritage 2013), a potentially more robust mortality estimation program has been released for use with the statistical analysis software Program R, called *facilityCMR*. This program offers several potential advantages over the Warren-Hicks Estimator including analyzing covariance between searcher efficiency and scavenger removal rates and allowing for analysis of carcass condition. We propose using the *facilityCMR* software in future analyses, as soon as searcher efficiency and scavenger removal trials are permitted. This would be used in lieu of the Warren-Hicks Estimator and Program MARK and better reflects current FWS guidance on mortality studies at solar facilities.

Post-construction Avian Mortality Monitoring Report for the Campo Verde Solar Project

---

Second Quarter 2014 (April, May, June)

Prepared By:

Heritage Environmental Consultants, LLC

1 Introduction

The Campo Verde Solar Project is a solar photovoltaic (PV) energy generating facility (Solar Energy Facility) and an associated electrical transmission line (Gen-Tie Line) in southern Imperial County, California. The solar project is located on private lands and the gen-tie line is located on private and federal lands managed by the Bureau of Land Management (BLM). These are referred to collectively as the "Project."

A Bird and Bat Conservation Strategy (BBCS) was prepared that addresses activities potentially occurring during construction and operation of the Project (Heritage 2013). The BBCS was reviewed and approved by the U.S. Fish and Wildlife Service (FWS), California Department of Fish and Wildlife (CDFW), and BLM. The purpose of the Campo Verde BBCS was to develop and implement a program to identify and avoid risks to avian and bat species that could result from construction and operation of the Project. The goal of this BBCS was to implement a series of best practices, in order to construct and operate the Project to avoid or reduce risk to birds, bats and their habitats.

The post-construction avian mortality monitoring program was set up to comply with the methodology prescribed in the BBCS (Heritage 2013). The methodology is described in Section 6.1 of the BBCS and was approved by the FWS and CDFW. Quarterly reports documenting results of the monitoring program are required for the first year of program, and annually thereafter. Monitoring began in October 2013 just after completion of construction. This report is the third of four quarterly reports for the first survey year.

1.1 Project Description

The general location of the Project is approximately 7 miles southwest of the city of El Centro, Imperial County, California (**Figure 1**). The Project is south of I-8, west of Drew Road, and northeast and south of the Westside Main Canal. The Project consists of two component parts: (i) the Solar Energy Facility and (ii) an approximately 0.9-mile, 230-kilovolt (kV) aboveground, electrical gen-tie line and associated facilities that electrically connects the Solar Energy Facility on private land with the Imperial Valley Substation (IV Substation) located on federal land managed by the BLM.

The Solar Energy Facility is approximately 1,443 acres in size and uses First Solar PV modules that are generally non-reflective and convert sunlight into direct current (DC) electricity. The DC output of multiple rows of PV modules is collected through one or more combiner boxes and directed to an inverter that converts the DC electricity to alternating current (AC) electricity. From the inverter, the generated energy flows to a transformer where it is stepped up to distribution level voltage (approximately 34.5 kV). Multiple transformers are connected in parallel via 34.5 kV lines to the Project substation, where the power is stepped up to 230 kV. This substation is located at the southern end of the Solar Energy Facility near Liebert Road. The Gen-Tie Line connects the Project substation to the Imperial Valley Substation approximately 0.9 miles to the south.

The Gen-Tie Line uses double-circuit tubular steel monopole structures. Tower structure heights range from 100 to 135 feet. One side of the double-circuit structures currently supports three two- bundle conductors and one shield wire. Typical overall structure widths are approximately 20 feet.

Project Facilities

2 Methods

Monitoring of the Project was performed in order to document and report avian mortalities and identify areas of concern by tracking both the specific locations where mortalities occur as well as the extent of such mortalities. The monitoring program for the Project is based on the FWS guidance entitled "Monitoring Migratory Bird Take at Solar Power Facilities: An Experimental Approach" (FWS 2012) with modifications, and was approved by FWS.

2.1 Transect Sampling

Sampling transects were established for both the gen-tie line and solar field. For each kilometer of Gen-Tie Line, 300-meter transects were randomly established along the Gen-Tie Line allowing for approximately 30 percent of the Gen-Tie Line to be sampled. Transects were positioned along the centerline of the Gen-Tie Line. For the Campo Verde Solar Energy Facility, transects were also positioned to result in approximately 30-percent coverage of the site with no less than eight transects placed within the solar field itself. Transect selection was systematic randomized. The entire perimeter of the panel arrays was also surveyed during each survey period in addition to the interior transects.

Transects were surveyed for 7 consecutive days each month and each transect was surveyed once daily. Because of the large number of transects, sampling periods were 14-days; the first half of transects were walked for 7- day period and the second half for another 7 day period. One qualified observer walked along the pre-determined transects searching for bird/bat carcasses. When a carcass was observed, a GPS location was recorded at the carcass, the species was identified, the perpendicular distance from the transect to the carcass was measured, and information regarding carcass condition per FWS (2012) was recorded using paper datasheets. Once data were collected at a carcass, the observer returned to the pre-determined transect and continued with the survey.

The original protocol stated that each carcass would be marked uniquely and inconspicuously with tape and permanent marker to assess "recapture" rates. However, both the state scientific collection permit (SCP) and the federal special purpose utility permit (SPUT) enabling surveyors to handle carcasses were still being processed during this sampling period so no mark-recapture data was collected. Scavenger removal trials and searcher efficiency trials were also not performed due to the lack of handling permits. Therefore, all estimates presented in this report represent mortality estimates that are uncorrected for observer bias and scavenger removal rates. Future reports will address these biases, once permits are approved by the FWS and CDFW.

2.2 Analysis

Two primary analyses were proposed for mortality estimation. The first analysis used Program DISTANCE to determine the most effective transect width to search for carcasses. Distance models examined a variety of detection functions and used Aikake's Information Criterion (AIC)[1] for model selection. Most modeling used a 5% upper truncation to remove outliers. Specific model components are discussed in **Section 3.2**.

The second analysis would use Program MARK to estimate total number of mortalities controlling for detection rate, scavenging rate, and proximity to Project components. However, as described above, handling permits have not been approved by either the FWS or CDFW. Thus, mark-recapture protocols could not be implemented. Future reports will contain a mark-recapture analysis, pending approval of handling permits. Alternative analysis packages may be considered (as opposed to Program MARK); see **Section 4.4** for additional discussion of potential statistical analyses.

---

[1] AIC measures the relative quality of a given model by assessing both the model's complexity as well as the model goodness-of-fit to the observed data. Lower AIC values indicate higher quality models. Typically AIC values are compared among several possible models to select the "best" model or models.

Project mortality estimates rely on measuring a daily mortality rate that can be used as the basis for all mortality estimates. To calculate the corrected project mortality estimate, we did not count all mortalities observed during day 1 of the 7-day search period under the assumption that the those mortalities represent "bleed through" from the period prior to 24 hours preceding the first search. To accurately generate a rate, all mortalities used for this analysis need to have occurred within the 24 hours preceding discovery. Mortalities observed during the subsequent 6 days were then up-corrected to adjust for time not searched (since the search period captured 6 out of 28, 30 or 31 days each month), producing a time-corrected mortality estimate for each month.

Because taxonomic analyses do not use a rate, but are instead only concerned with the overall breakdown in mortalities, these analyses used all recorded mortality data, including those mortalities observed during day 1 of the 7-day search period. The use of these data from day one assumes that there is not persistence bias for different taxa of birds. Once scavenger removal trials are approved, this assumption can be tested and analyses will be adjusted if necessary.

3 Results

3.1 Overall Mortalities Observed

Second quarter surveys for 2014 were conducted from April 14-27, 2014; May 9-22, 2014; and, June 14-27, 2014. A total of 10 avian mortalities were recorded. Three (3) of these observed mortalities were recorded as "feather spots". **Table 1** provides a breakdown of mortalities by sampling period.

Table 1 – Observed Mortalities by Sampling Period

Mortality Type	April (4/14/14 – 4/27/14)	May (5/9/14 – 5/22/14)	June (6/14/14 – 6/27/14)	Q2 2014 TOTAL
Feather Spot Mortalities	2	0	1	3
Non-Feather Spot Mortalities	2	1	4	7
Total Mortalities	*4*	*1*	*5*	*10*

The inclusion of feather spots as observed mortalities is based on standard mortality monitoring protocols, which were largely developed for the wind energy industry. At wind energy facilities, the speed of the spinning blades can result in mortalities that leave very little detectible carcass behind, including only feather spots. Inclusion of feather spots as recorded mortalities at these facilities was intended to conservatively include mortalities caused by blade strikes that might otherwise go unrecorded. Potential bias resulting from the inclusion of feather spots in mortality data can arise from feather spots meeting the definition of a mortality but not actually resulting from an avian mortality. This bias can lead to overestimates of mortality rates. This bias is problematic in situations where feathers are commonly deposited in non-mortality related events but get included as incidents of avian morality (e.g. in and around common roost or perch sites, near active nests, etc.). Feather spots may also be caused by predation or attempted-predation events within a survey area. Based on the large proportion of feather spots observed during the Q4 2013 and Q2 2014 surveys (63% and 41%, respectively), observers used greater discretion when encountering feather spots to help mitigate this bias. Feather spots that strongly indicated a deposition of feathers that was unrelated to an avian mortality or injury were excluded from the database; in instances where observers were uncertain, the feathers spots were recorded as mortalities in order to be conservative. All of the following analyses present results that both include and exclude feather spots to present the full range of possible mortalities.

3.2 Effective Transect Width

DISTANCE analyses were performed using the data pooled across the three-month sampling period and **Table 2** presents the results of the DISTANCE analysis. It is important to note that none of the models fit the data well and model parameters were constrained to obtain monotonicity[2] in several cases. Additionally, sample sizes were very small during Q2 of 2014, further limiting the reliability of the DISTANCE analysis. Models were run using all observed mortalities since sample sizes were far too small to run subdivided models.

---

[2] DISTANCE analyses rely on the modeling of a detection function. This detection function models the change in probability of detecting a carcass as the distance from the transect increases. This type of modelling relies on the assumption that the detection function is monotonic. Monotonic means that the probability of detection *only* changes in one direction (decreases) with increasing distance from the transect. If the detection probability goes up and down as distance from the transect increases, then the results violate this assumption of monotonicity. Program DISTANCE automatically constrains certain model parameters to obtain monotonicity but the resulting model may have a poor fit to the observed data.

The a priori[3] estimate of effective transect width was approximately 7.5 meters (this represents the width of two panel rows measured from the bottom of the panel immediately north of the designated transects to the bottom of the second panel to the south of the transect). Generally, the most likely models were consistent with or exceeded that assumption. Sample sizes were small for all models run this quarter and model results should be used with a high degree of caution (e.g. note that modeled density was rounded to 0.00 for all model definitions indicating very low densities – i.e. low sample sizes).

Table 2 – Distance Analysis Results – includes feather spots

Model Definition	# of Parameters	AIC	ΔAIC	Density (mortalities per hectare)	95% CI	Effective Transect Width (m)
Hazard – Cosine*	2	70.16	0.00	0.00	0.00-0.00	8.45
Uniform – Cosine*	3	75.93	5.76	0.00	0.00-0.00	20.55
Uniform – Polynomial*	4	78.49	8.33	0.00	0.00-0.00	22.05
Half Normal – Polynomial	1	79.08	8.92	0.00	0.00-0.00	29.19
Half Normal – Hermite	1	79.08	8.92	0.00	0.00-0.00	29.19

*Some parameters were constrained to obtain monotonicity.

3.3 Searcher Bias

As described above, permits allowing observers to handle bird carcasses had not been issued at the time of these surveys. As such, no searcher bias estimates were generated and overall mortality estimates were not adjusted to reflect searcher bias.

3.4 Scavenger Removal Bias

As described above, permits allowing observers to handle bird carcasses had not been issued at the time of these surveys. As such, no scavenger removal trials were completed and overall mortality estimates were not adjusted to reflect scavenger removal bias.

3.5 Corrected Project Mortality Estimate

Results from surveys conducted each month were used to generate discrete mortality estimates for each month surveyed. Monthly and overall project mortality estimates only used data from search days 2-7 (see **Section 2.2**). Monthly mortality estimates were used in order to detect seasonal variations in mortality rates. Also, data are presented to reflect estimates with and without feather spots, as discussed earlier. For the remainder of this section, mortality values are presented as "number of mortalities excluding feather spots"/"number of mortalities inclusive of feather spots".

While results of the DISTANCE analyses were less than conclusive, they were at least consistent with the a priori assumption of a minimum 7.5-meter effective transect width. Past quarterly DISTANCE analyses for this study have also supported the validity of the 7.5-meter transect. Transect layout, in consideration of this assumed effective transect width, was designed to sample 30% of the overall PV array area. The time-corrected mortality estimates for each month were again up-corrected to account for the area not surveyed. Since no searcher efficiency or scavenger removal bias corrections were performed, this time- and area-corrected mortality estimate represents the overall monthly project mortality estimate. Mortality

---

[3] "A priori" hypotheses are those hypothesis developed based on a theoretical and logical understanding of the system in question and not based on empirical results. That is, a priori hypothesis are those generated before any results have been collected.

estimates were rounded to the nearest whole number. **Table 4** summarizes the corrected mortality estimates by month.

3.5.1 April Mortalities

A total of 1/3 mortalities were detected during days 2-7 of the April surveys. Correcting for time (the 6 day survey period represents approximately 20% of the total days in April) and area surveyed, the overall monthly project mortality estimate for April was 17/50.

3.5.2 May Mortalities

A total of 1/1 mortalities were detected during days 2-7 of the May surveys. Correcting for time (the 6 day survey period represents approximately 19% of the total days in May) and area surveyed, the overall monthly project mortality estimate for May was 17/17.

3.5.3 June Mortalities

A total of 3/3 mortalities were detected during days 2-7 of the June surveys. Correcting for time (the 6 day survey period represents approximately 20% of the total days in June) and area surveyed, the overall monthly project mortality estimate for June was 50/50.

3.5.4 Second Quarter 2014 Corrected Mortality Estimates

After applying time and area corrections to the mortality counts for each month the overall project mortality estimate for the second quarter of 2014 is 84/117 birds.

Table 4 – Corrected Mortalities by Month

	April		May		June		Q2 Totals	
	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots
Raw Mortality Count (days 2-7)	1	3	1	1	3	3	5	7
Corrected Mortality Estimate	17	50	17	17	50	50	84	117

3.6 Taxonomic Composition of Observed Mortalities

The following analyses use all observed mortalities including those detected on search day 1 since the taxonomic composition is not a rate-dependent analysis (see **Section 2.2**).

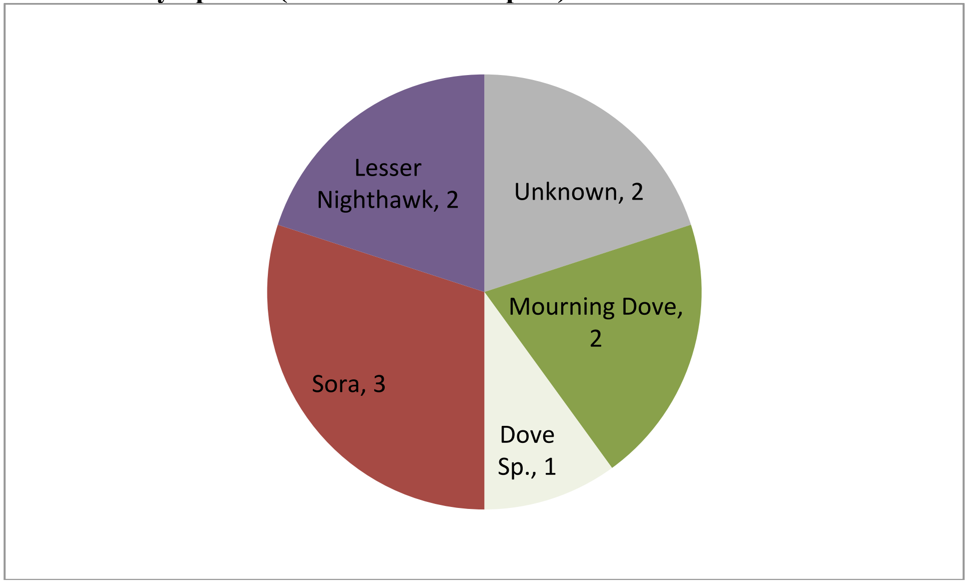
Table 5 – Raw Mortalities by Month (includes data from all search days)

	April		May		June		Q2 Totals	
	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots
Raw Mortality Count (days 1-7)	2	4	1	1	4	5	7	10

3.6.1 Mortalities Including Feather Spots

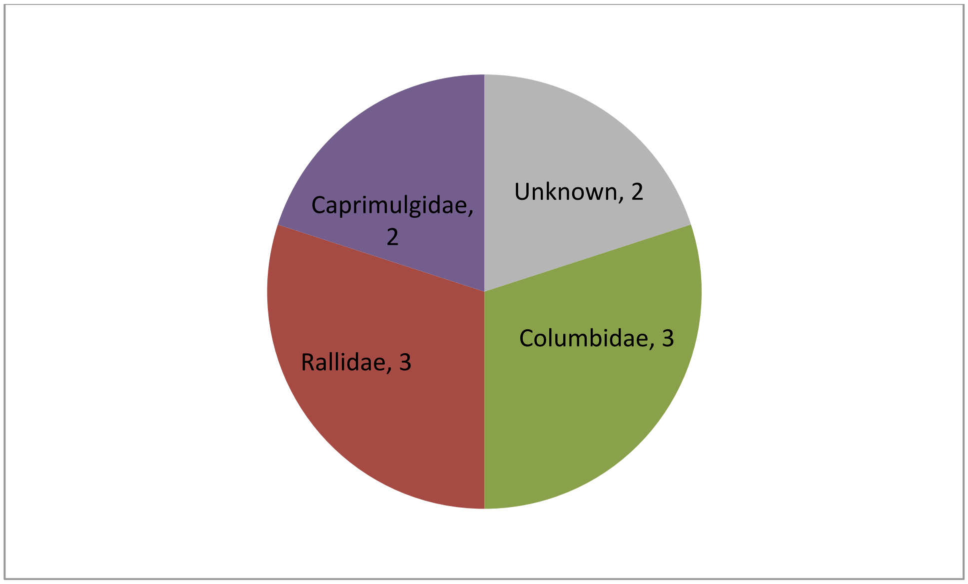
A total of 10 mortalities were observed when feather spots were included in the data set. Two (2) of these mortalities (20%) could not be identified to species. Of the 8 carcasses that could be identified to species, the most commonly observed species were Sora (*Porzana Carolina*; 3 mortalities; 37.5% of mortalities identified to species level), Mourning Dove (*Zenaida macroura*; 2 mortalities; 25% of mortalities identified to species level), and Lesser Nighthawk (*Chordeiles acutipennis*; 2 mortalities; 25% of mortalities identified to species level). **Figure 2** presents the breakdown of observed mortalities by species.

Figure 2 – Mortalities by Species (includes feather spots)



Eight (8) of the 10 observed mortalities could be identified to the family level. Of these 8 mortalities, the families Rallidae (3 mortalities; 37.5% of mortalities identified to family level) and Columbidae (3 mortalities; 37.5% of mortalities identified to family level) were the most commonly observed mortalities. **Figure 3** presents the breakdown of observed mortalities by family.

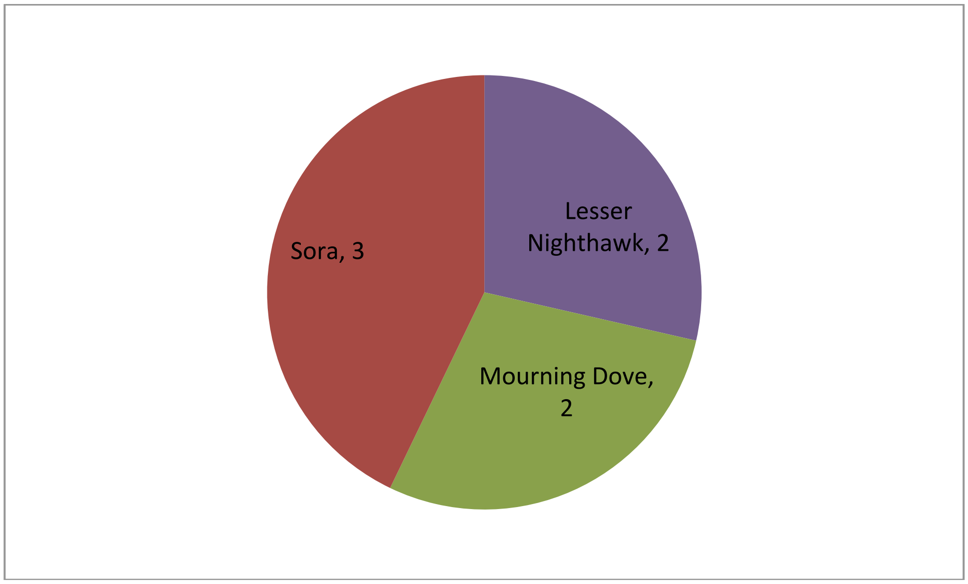
Figure 3 – Mortalities by Family (includes feather spots)



3.6.2 Mortalities Excluding Feather Spots

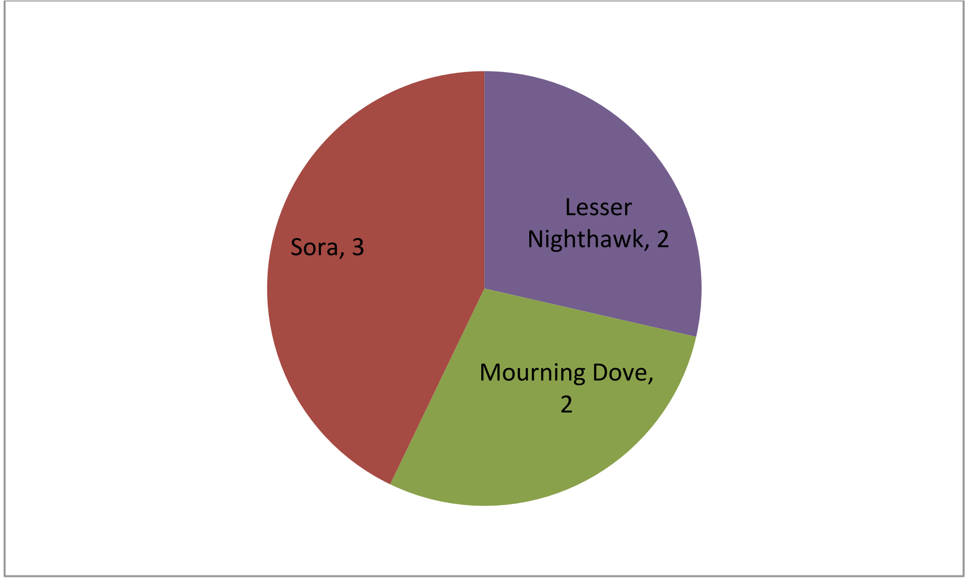
A total of 7 mortalities were observed when feather spots were excluded from the data set. All 7 of these mortalities (100%) could be identified to species. Of these 7 carcasses, the most commonly observed species was Sora (3 mortalities; 42.9% of mortalities identified to species). **Figure 4** presents the breakdown of observed mortalities by species.

Figure 4 - Mortalities by Species (excludes feather spots)



All 7 of the observed mortalities could be identified to the family level. Of these mortalities, the family Rallidae (3 mortalities; 42.9% of mortalities identified to family level) was the most commonly observed mortality. **Figure 5** presents the breakdown of observed mortalities by family.

Figure 5 – Mortalities by Family (excludes feather spots)



4 Discussion

4.1 Mortality Estimates

Searcher efficiency and scavenger removal trials can only result in up-correcting results (since searchers cannot detect >100% of carcasses and scavengers are unlikely to deposit carcasses within a survey area). Because searcher efficiency and scavenger removal trials were not performed during the second quarter surveys, the degree of underestimation is unknown. As soon as the Campo Verde Project receives a SPUT permit from FWS and a SCP from CDFW, searcher efficiency and scavenger removal trials will begin.

4.2 Seasonal Variations

When the estimated mortality rates included feather spot mortalities there was strong variation month to month, than as been observed in past quarterly summaries. May mortalities only accounted for 15% of all mortalities, whereas April and June each accounted for 60% each. When feather spots were excluded, mortality rates were more consistent month to month, only ranging between 15-43% each month. It should be noted that the sample size of observed mortalities was very low this quarter, making these types of analyses difficult to achieve high confidence levels.

4.3 Recommended Methodological Changes

The following changes are recommended to improve survey efficiency and accuracy as well as to improve data collection and analysis.

1. Searcher Efficiency and Scavenger Removal Bias – The results presented in this report are uncorrected for searcher efficiency and scavenger removal. Searcher efficiency at this site is likely very high (near 100%) given the level ground and almost entirely unvegetated environment. As such, the searcher efficiency bias is unlikely to have resulted in a significant underestimate of mortality. However, scavenger removal rates are unknown and could be a source of bias. Numerous potential avian and mammalian scavengers are known to occur in and around the project site. Until scavenger removal trials are performed, the magnitude of this source of bias is unknown. As soon as state and federal permits are approved, these trials will be initiated.
2. Alternative Statistical Analysis Packages – Since the publication of the project BBCS (Heritage 2013), a potentially more robust mortality estimation program has been released for use with the statistical analysis software Program R, called *facilityCMR*. This program offers several potential advantages over the Warren-Hicks Estimator including analyzing covariance between searcher efficiency and scavenger removal rates and allowing for analysis of carcass condition. We propose using the *facilityCMR* software in future analyses, as soon as searcher efficiency and scavenger removal trials are permitted. This would be used in lieu of the Warren-Hicks Estimator and Program MARK and better reflects current FWS guidance on mortality studies at solar facilities.

Post-construction Avian Mortality Monitoring Report for the Campo Verde Solar Project

Fourth Quarter 2013

Prepared By:

Heritage Environmental Consultants, LLC

1 Introduction

The Campo Verde Solar Project is a solar photovoltaic (PV) energy generating facility (Solar Energy Facility) and an associated electrical transmission line (Gen-Tie Line) in southern Imperial County, California. The solar project is located on private lands and the gen-tie line is located on private and federal lands managed by the Bureau of Land Management (BLM). These are referred to collectively as the "Project."

A Bird and Bat Conservation Strategy (BBCS) was prepared that addresses activities potentially occurring during construction and operation of the Project (Heritage 2013). The BBCS was reviewed and approved by the U.S. Fish and Wildlife Service (FWS), California Department of Fish and Wildlife (CDFW), and BLM. The purpose of the Campo Verde BBCS was to develop and implement a program to identify and avoid risks to avian and bat species that could result from construction and operation of the Project. The goal of this BBCS was to implement a series of best practices, in order to construct and operate the Project to avoid or reduce risk to birds, bats and their habitats.

The post-construction avian mortality monitoring program was set up to comply with the methodology prescribed in the BBCS (Heritage 2013). The methodology is described in Section 6.1 of the BBCS and was approved by the FWS and CDFW. Quarterly reports documenting results of the monitoring program are required for the first year of program, and annually thereafter. Monitoring began in October 2013 just after completion of construction. This report is the first of four quarterly reports.

1.1 Project Description

The general location of the Project is approximately 7 miles southwest of the city of El Centro, Imperial County, California (**Figure 1**). The Project is south of I-8, west of Drew Road, and northeast and south of the Westside Main Canal. The Project consists of two component parts: (i) the Solar Energy Facility and (ii) an approximately 0.9-mile, 230-kilovolt (kV) aboveground, electrical gen-tie line and associated facilities that electrically connects the Solar Energy Facility on private land with the Imperial Valley Substation (IV Substation) located on federal land managed by the BLM.

The Solar Energy Facility is approximately 1,443 acres in size and uses First Solar PV modules that are generally non-reflective and convert sunlight into direct current (DC) electricity. The DC output of multiple rows of PV modules is collected through one or more combiner boxes and directed to an inverter that converts the DC electricity to alternating current (AC) electricity. From the inverter, the generated energy flows to a transformer where it is stepped up to distribution level voltage (approximately 34.5 kV). Multiple transformers are connected in parallel via 34.5 kV lines to the Project substation, where the power is stepped up to 230 kV. This substation is located at the southern end Solar Energy Facility near Liebert Road. The Gen-Tie Line connects the Project substation to the Imperial Valley Substation approximately 0.9 miles to the south.

The Gen-Tie Line uses double-circuit tubular steel monopole structures. Tower structure heights range from 100 to 135 feet. One side of the double-circuit structures currently supports three two- bundle conductors and one shield wire. Typical overall structure widths are approximately 20 feet.

Project Facilities

2 Methods

Monitoring of the Project was performed in order to document and report avian mortalities and identify areas of concern by tracking both the specific locations where mortalities occur as well as the extent of such mortalities. The monitoring program for the Project is based on the FWS guidance entitled "Monitoring Migratory Bird Take at Solar Power Facilities: An Experimental Approach" (FWS 2012) with modifications, and was approved by FWS.

2.1 Transect Sampling

Sampling transects were established for both the gen-tie line and solar field. For each kilometer of Gen-Tie Line, 300-meter transects were randomly established along the Gen-Tie Line allowing for approximately 30 percent of the Gen-Tie Line to be sampled. Transects were positioned along the centerline of the Gen-Tie Line. For the Campo Verde Solar Energy Facility, transects were also positioned to result in approximately 30-percent coverage of the site with no less than eight transects placed within the solar field itself. Transect selection was systematic randomized. The entire perimeter of the panel arrays was also surveyed during each survey period in addition to the interior transects.

Transects were surveyed for 7 consecutive days each month and each transect was surveyed once daily. Because of the large number of transects, sampling periods were 14-days; the first half of transects were walked for 7- day period and the second half for another 7 day period. One qualified observer walked along the pre-determined transects searching for bird/bat carcasses. When a carcass was observed, a GPS location was recorded at the carcass (for DISTANCE analysis), the species was identified, and information regarding carcass condition per FWS (2012) was recorded using paper datasheets. Once data were collected at a carcass, the observer returned to the pre-determined transect and continued with the survey.

The original protocol stated that each carcass would be marked uniquely and inconspicuously with tape and permanent marker to assess "recapture" rates. However, both the state scientific collection permit (SCP) and the federal special purpose utility permit (SPUT) enabling surveyors to handle carcasses were still being processed during this sampling period so no mark-recapture data was collected. Scavenger removal trials and searcher efficiency trials were also not performed due to the lack of handling permits. Therefore, all estimates presented in this report represent mortality estimates that are uncorrected for observer bias and scavenger removal rates. Future reports will address these biases, once permits are approved by the FWS and CDFW.

2.2 Analysis

Two primary analyses were proposed for mortality estimation. The first analysis used Program DISTANCE to determine the most effective transect width to search for carcasses. Distance models examined a variety of detection functions and used Aikake's Information Criterion (AIC)[1] for model selection.

The second analysis would use Program MARK to estimate total number of mortalities controlling for detection rate, scavenging rate, and proximity to Project components. However, as described above, handling permits have not been approved by either the FWS or CDFW, thus mark-recapture protocols could not be implemented. Future reports will contain a mark-recapture analysis, pending approval of

---

[1] AIC measures the relative quality of a given model by assessing both the model's complexity as well as the model goodness-of-fit to the observed data. Lower AIC values indicate higher quality models. Typically AIC values are compared among several possible models to select the "best" model or models.

handling permits. Alternative analysis packages may be considered (as opposed to Program MARK); see **Section 4.3** for additional discussion of potential statistical analyses.

Project mortality estimates rely on measuring a daily mortality rate that can be used as the basis for all mortality estimates. To calculate the corrected project mortality estimate, we did not count all mortalities observed during day 1 of the 7-day search period under the assumption that the those mortalities represent "bleed through" from the period prior to 24 hours preceding the first search. To accurately generate a rate, all mortalities used for this analysis need to have occurred within the 24 hours preceding discovery. Mortalities observed during the subsequent 6 days were then up-corrected to adjust for time not searched (since the search period captured 6 out of 30 or 31 days each month), producing a time-corrected mortality estimate for each month.

Because taxonomic analyses do not use a rate, but are instead only concerned with the overall breakdown in mortalities, these analyses used all recorded mortality data, including those mortalities observed during day 1 of the 7-day search period. The use of these data from day one assumes that there is not persistence bias for different types of birds. Once scavenger removal trials are approved, this assumption can be tested and analyses will be adjusted if necessary.

3 Results

3.1 Overall Mortalities Observed

Fourth quarter surveys for 2013 were conducted from October 21 – November 3, 2013; November 11-23, 2013; and, December 7-20, 2013. A total of 36 avian mortalities were recorded. Twenty-three (23) of these observed mortalities were recorded as "feather spots" (defined as 10 or more feathers within a $1m^2$ area). All feather spots were assumed to be mortalities, though it is unlikely that they all represent a mortality. **Table 1** provides a breakdown of mortalities by sampling period.

Table 1 – Observed Mortalities by Sampling Period

Mortality Type	October (10/21/13 – 11/3/13)	November (11/11/13 – 11/23/13)	December (12/7/13 – 12/20/13)	Q4 2013 TOTAL
Feather Spot Mortalities	6	15	2	23
Non-Feather Spot Mortalities	8	2	3	13
Total Mortalities	*14*	*17*	*5*	*36*

The inclusion of feather spots as observed mortalities is based on standard mortality monitoring protocols, which were largely developed for the wind energy industry. At wind energy facilities, the speed of the spinning blades can result in mortalities that leave very little detectible carcass behind, including only feather spots. Inclusion of feather spots as recorded mortalities at these facilities was intended to conservatively include mortalities caused by blade strikes that might otherwise go unrecorded. Potential bias resulting from the inclusion of feather spots in mortality data can arise from feather spots meeting the definition of a mortality (in this case >10 feathers within $1m^2$) but not actually resulting from an avian mortality. This bias can lead to overestimates of mortality rates. This bias is problematic in situations where feathers are commonly deposited in non-mortality related events but get included as incidents of avian morality (e.g. in and around common roost or perch sites, near active nests, etc.). Feather spots may also be caused by predation or attempted-predation events within a survey area. In these cases, the mortality is recorded but the causal relation of that mortality to a project may be misrepresented.

A large proportion of mortalities recorded during the 2013 Q4 surveys were detected as feather spots (over 63% overall and over 88% of mortalities recorded in November). It is unclear if some or all of these feather spots can be accurately attributed to project-related causes, or whether they were actual mortalities. Unlike with wind energy facilities, there are not anticipated project-related mortality hazards that could be expected to result in only feather spot remains. Furthermore, during mortality surveys, biologists routinely observed multiple species perching and roosting on the panels, often times depositing large numbers of feathers. Wintering raptors are also common in the agricultural areas of the Imperial Valley and were routinely observed in and around the panel arrays. Thus, normal perching, roosting, predation and scavenging could account for a significant number of the observed feather spots. Conversely, some of the feather spots were identified as species that would not be expected to naturally occur within the panel arrays and were not previously observed in the interior of the agricultural fields during the pre-construction avian surveys (Heritage 2012). For these reasons, all of the following analyses present results that both include and exclude feather spots to present the full range of possible mortalities. Additional recommendations regarding the use of feather spot data in future surveys can be found in **Section 4.3**.

3.2 Effective Transect Width

DISTANCE analyses were performed using the data pooled across the three-month sampling period and **Tables 2 and 3** present the results of the DISTANCE analysis. It is important to note that none of the models fit the data well and model parameters were constrained to obtain monotonicity[2] in several cases. DISTANCE model fitting issues are discussed in greater detail in **Section 4.3**. The a priori[3] estimate of effective transect width was approximately 7.5 meters (this represents the width of two panel rows measured from the bottom of the panel immediately north of the designated transects to the bottom of the second panel to the south of the transect). Generally, the most likely models were consistent with that assumption. Corrections to the methods used to assess perpendicular distance are expected to improve model fit in future analyses and allow for a more accurate assessment of effective transect width (**Section 4.3**).

Table 2 – Distance Analysis Results – without feather spots

Model Definition	# of Parameters	AIC	ΔAIC	Density (mortalities per hectare)	95% CI	Effective Transect Width (m)
Hazard – Cosine*	2	73.19	0.00	0.150	0.031-0.721	6.24
Uniform – Cosine*	1	73.79	0.61	0.065	0.032-0.132	14.34
Uniform – Polynomial	0	74.19	1.00	0.043	0.077-0.305	22.00

Half Normal – Hermit*	1	74.41	1.22	0.064	0.129-0.369	14.76

*Some parameters were constrained to obtain monotonicity.

---

[2] DISTANCE analyses rely on the modeling of a detection function. This detection function models the change in probability of detecting a carcass as the distance from the transect increases. This type of modelling relies on the assumption that the detection function is monotonic. Monotonic means that the probability of detection *only* changes in one direction (decreases) with increasing distance from the transect. If the detection probability goes up and down as distance from the transect increases, then the results violate this assumption of monotonicity. Program DISTANCE automatically constrains certain model parameters to obtain monotonicity but the resulting model may have a poor fit to the observed data.

[3] "A priori" hypotheses are those hypothesis developed based on a theoretical and logical understanding of the system in question and not based on empirical results. That is, a priori hypothesis are those generated before any results have been collected.

Table 3 – Distance Analysis Results – with feather spots

Model Definition	# of Parameters	AIC	ΔAIC	Density (mortalities per hectare)	95% CI	Effective Transect Width
Hazard – Cosine*	2	196.39	0.00	0.394	0.175-0.885	6.75
Uniform – Cosine*	3	199.21	2.82	0.303	0.182-0.506	8.76
Uniform – Polynomial*	5	202.43	6.04	0.318	0.186-0.543	8.37
Half Normal – Polynomial	1	202.90	6.52	0.216	0.139-0.337	12.28
Half Normal – Hermit	1	202.90	6.52	0.216	0.139-0.337	12.28

*Some parameters were constrained to obtain monotonicity.

3.3 Searcher Bias

As described above, permits allowing observers to handle bird carcasses were not in place during these surveys. As such, no searcher bias estimates were generated and overall mortality estimates were not adjusted to reflect searcher bias.

3.4 Scavenger Removal Bias

As described above, permits allowing observers to handle bird carcasses were not in place during these surveys. As such, no scavenger removal trials were completed and overall mortality estimates were not adjusted to reflect scavenger removal bias.

3.5 Corrected Project Mortality Estimate

Results from surveys conducted each month were used to generate discrete mortality estimates for each month surveyed. Monthly and overall project mortality estimates only used data from search days 2-7 (see **Section 2.2**). Monthly mortality estimates were used in order to detect seasonal variations in mortality rates. Also, data are presented to reflect estimates with and without feather spots as discussed earlier. For the remainder of this section, mortality values are presented as "number of mortalities excluding feather spots"/"number of mortalities inclusive of feather spots".

While results of the DISTANCE analyses were less than conclusive, they were at least consistent with the a priori assumption of a minimum 7.5 meter effective transect width. Transect layout, in consideration of this effective transect width, was designed to sample 30% of the overall PV array area. The time-corrected mortality estimates for each month were again up-corrected to account for the area not surveyed. Since no searcher efficiency or scavenger removal bias corrections were performed, this time- and area-corrected mortality estimate represents the overall monthly project mortality estimate. Mortality estimates were rounded to the nearest whole number. **Table 4** summarizes the corrected mortality estimates by month.

3.5.1 October Mortalities

A total of 6/11 mortalities were detected during days 2-7 of the October surveys. Correcting for time (the 6 day survey period represents approximately 19% of the total days in October) and area surveyed, the overall monthly project mortality estimate for October was 103/189.

3.5.2 November Mortalities

A total of 2/9 mortalities were detected during days 2-7 of the November surveys. Correcting for time (the 6 day survey period represents approximately 20% of the total days in November) and area surveyed, the overall monthly project mortality estimate for November was 33/150.

3.5.3 December Mortalities

A total of 3/5 mortalities were detected during days 2-7 of the December surveys. Correcting for time (the 6 day survey period represents approximately 19% of the total days in December) and area surveyed, the overall monthly project mortality estimate for December was 52/86.

3.5.4 Fourth Quarter 2013 Corrected Mortality Estimates

After applying time and area corrections to the mortality counts for each month the overall project mortality estimate for the fourth quarter of 2013 is 188/426 birds.

Table 4 – Corrected Mortalities by Month

	October		November		December		Q4 Totals	
	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots
Raw Mortality Count (days 2-7)	6	11	2	9	3	5	11	25
Corrected Mortality Estimate	103	189	33	150	52	86	188	426

3.6 Taxonomic Composition of Observed Mortalities

The following analyses use all observed mortalities including those detected on search day 1 since the taxonomic composition is not a rate-dependent analysis (see **Section 3.2**).

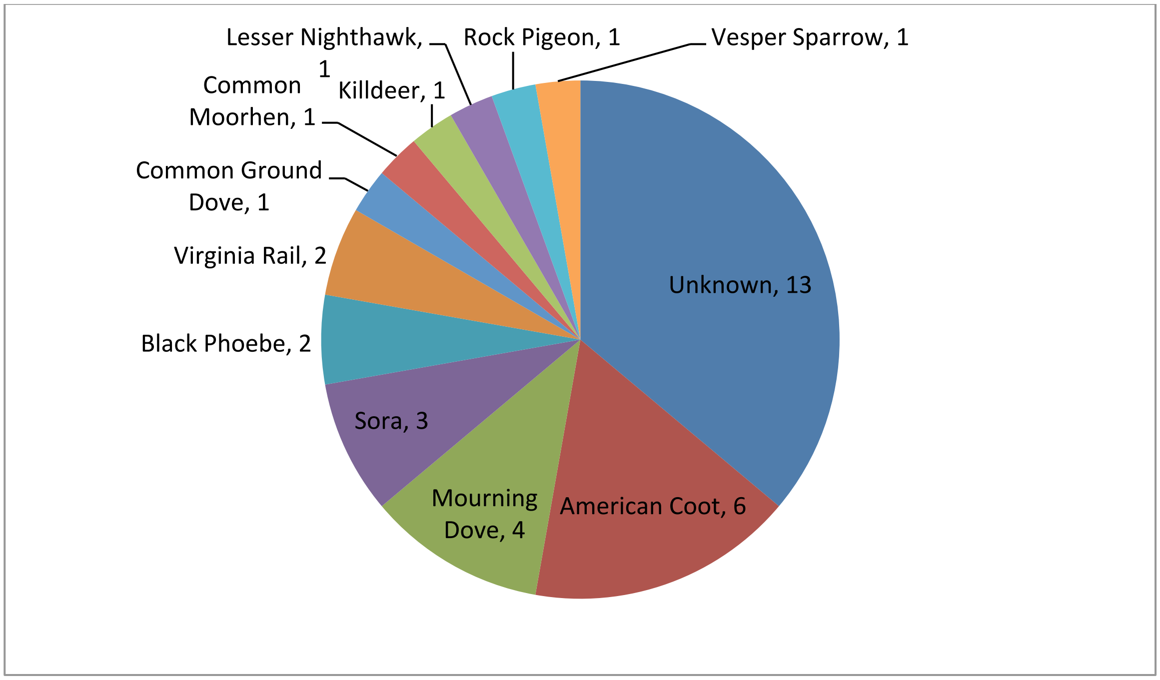
Table 5 – Raw Mortalities by Month (includes data from all search days)

	October		November		December		Q4 Totals	
	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots
Raw Mortality Count (days 1-7)	8	14	2	17	3	5	13	36

3.6.1 Mortalities Including Feather Spots

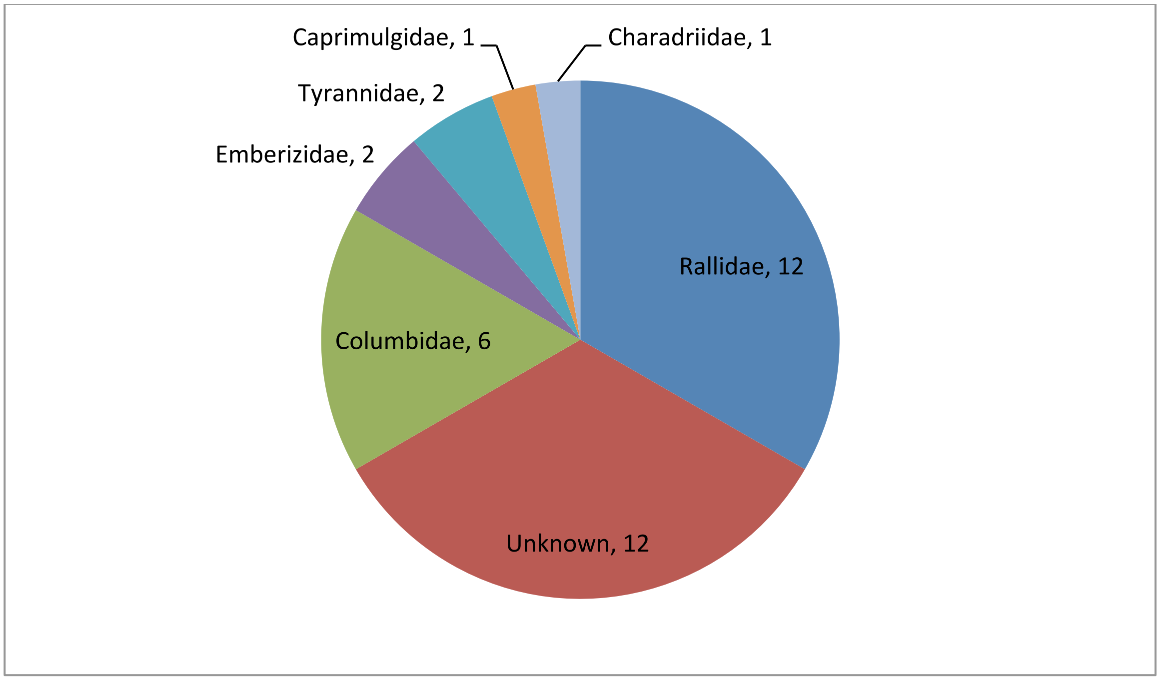
A total of 36 mortalities were observed when feather spots were included in the data set. Thirteen (13) of these mortalities (36%) could not be identified to species. Of the 23 carcasses that could be identified to species, the most commonly observed species were American Coot (*Fulica Americana*; 6 mortalities; 26% of mortalities identified to species level), Mourning Dove (*Zenaida macroura*; 4 mortalities; 18% of mortalities identified to species level), and Sora (*Porzana Carolina*; 3 mortalities; 13% of mortalities identified to species level). **Figure 2** presents the breakdown of observed mortalities by species.

Figure 2 – Mortalities by Species (includes feather spots)



Twenty-four (24) of the 36 observed mortalities could be identified to the family level. Of these 24 mortalities, the families Rallidae (12 mortalities; 50% of mortalities identified to family level), Columbidae (6 mortalities; 25% of mortalities identified to family level), and Emberizidae (2 mortalities; 9% of mortalities identified to family level) were the most commonly observed mortalities. **Figure 3** presents the breakdown of observed mortalities by family.

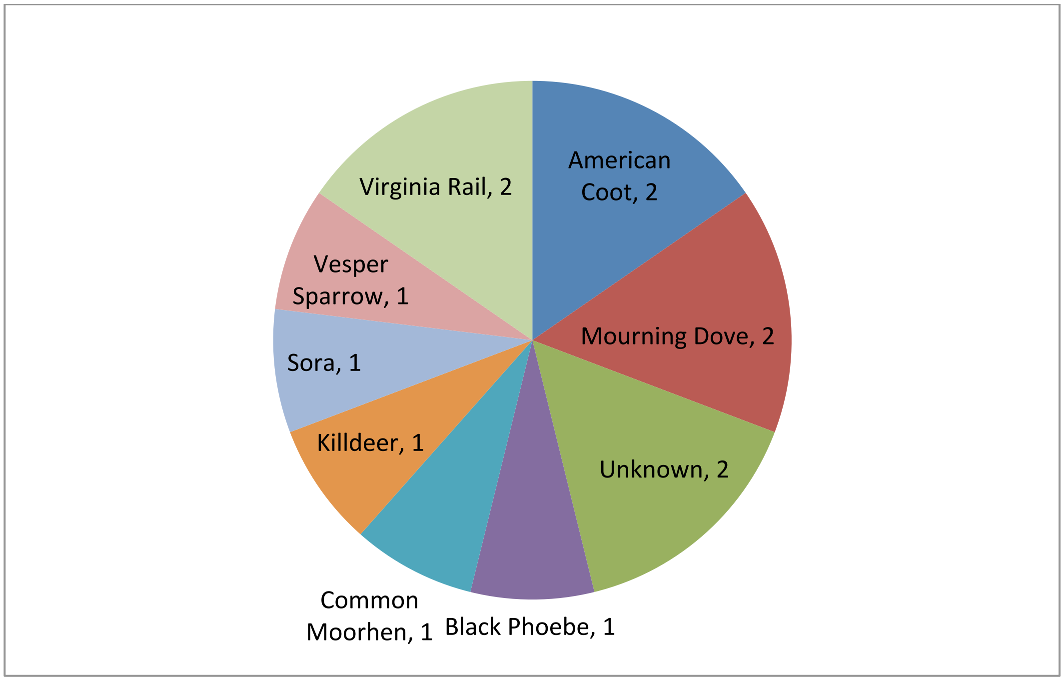
Figure 3 – Mortalities by Family (includes feather spots)



3.6.2 Mortalities Excluding Feather Spots

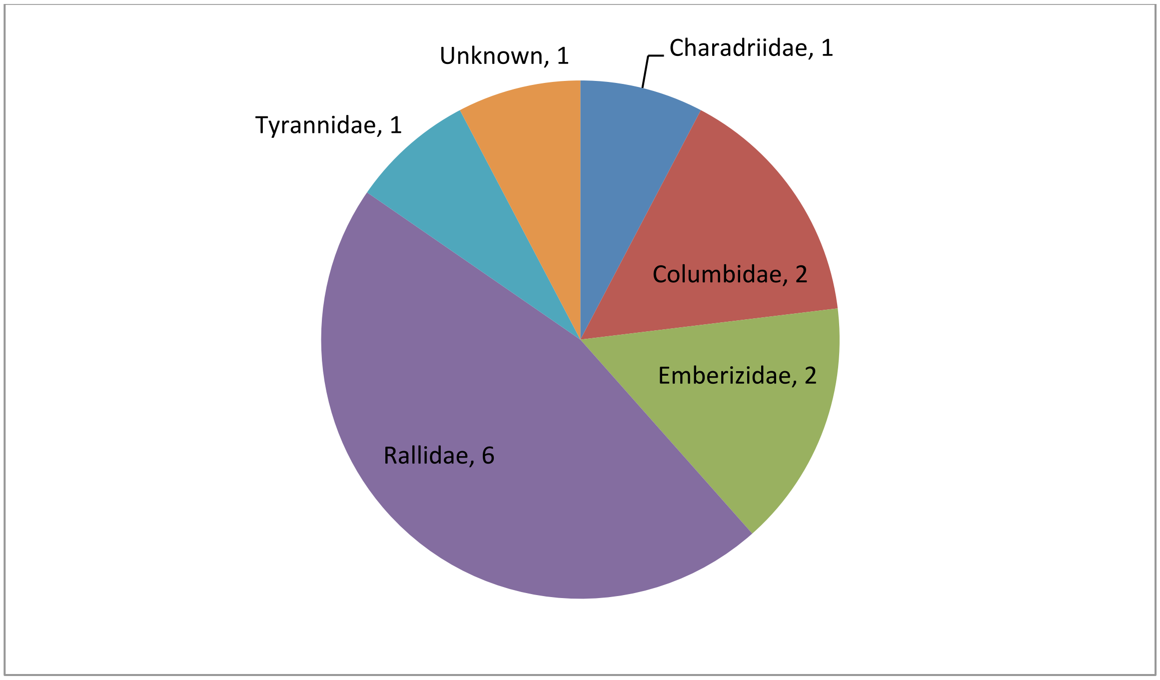
A total of 13 mortalities were observed when feather spots were excluded from the data set. Two (2) of these mortalities (15%) could not be identified to species. Of the 11 carcasses that could be identified to species, the most commonly observed species were American Coot (2 mortalities; 18% of mortalities identified to species level), Mourning Dove (2 mortalities; 18% of mortalities identified to species level), and Virginia Rail (*Rallus limicola*; 2 mortalities; 18% of mortalities identified to species). **Figure 4** presents the breakdown of observed mortalities by species.

Figure 4 - Mortalities by Species (excludes feather spots)



Twelve (12) of the 13 observed mortalities could be identified to the family level. As with the dataset that included feather spots, of these 12 mortalities, the families Rallidae (6 mortalities; 50% of mortalities identified to family level), Columbidae (2 mortalities; 17% of mortalities identified to family level), and Emberizidae (2 mortalities; 17% of mortalities identified to family level) were the most commonly observed mortalities. **Figure 5** presents the breakdown of observed mortalities by family.

Figure 5 – Mortalities by Family (excludes feather spots)



4 Discussion

4.1 Mortality Estimates

Searcher efficiency and scavenger removal trials can only result in up-correcting results (since searchers cannot detect >100% of carcasses and scavengers do not deposit carcasses within a survey area). Because searcher efficiency and scavenger removal trials were not performed during the fourth quarter surveys, the degree of underestimation is unknown. As soon as the Campo Verde Project receives a SPUT permit from FWS and a SCP from CDFW, searcher efficiency and scavenger removal trials will begin. There are no published reports or peer-reviewed articles documenting systematic mortality surveys at a solar photovoltaic facility to compare to the Campo Verde Project.

4.2 Seasonal Variations

A large proportion of the fourth quarter 2013 mortalities were observed in October (55% excluding feather spots; 44% including feather spots). Mortality rates appeared to decline with time. December only accounted for 28% of mortalities (excluding feather spots; 20% when feather spots were included).

4.3 Recommended Methodological Changes

The following changes are recommended to improve survey efficiency and accuracy as well as to improve data collection and analysis.

1. Direct Measurement of Perpendicular Distance – Per the FWS protocol (FWS 2012), a geographic information system was used to measure the perpendicular distance a carcass was located from a transect line. Given the relatively small effective transect width (~7.5m) compared to typical GPS accuracy (~3m), we feel that this method is unlikely to be the most accurate. For subsequent surveys we propose directly measuring the perpendicular distance in the field. The errors in measurement are suspected to have contributed to the lack of monotonicity in the model results.
2. Searcher Efficiency and Scavenger Removal Bias – The results presented in this report are uncorrected for searcher efficiency and scavenger removal. Searcher efficiency at this site is likely very high (near 100%) given the level ground and almost entirely unvegetated environment. As such, the searcher efficiency bias is unlikely to have resulted in a significant underestimate of mortality. However, scavenger removal rates are unknown and could be a source of bias. Numerous potential avian and mammalian scavengers are known to occur in and around the project site. Until scavenger removal trials are performed, the magnitude of this source of bias is unknown. As soon as state and federal permits are approved, these trials will be initiated.
3. Alternative Statistical Analysis Packages – Since the publication of the project BBCS (Heritage 2013), a potentially more robust mortality estimation program has been released for use with the statistical analysis software Program R, called facilityCMR. This program offers several potential advantages over the Warren-Hicks Estimator including analyzing covariance between searcher efficiency and scavenger removal rates and allowing for analysis of carcass condition. We propose using the facilityCMR software in future analyses, as soon as searcher efficiency and scavenger removal trials are permitted. This would be used in lieu of the Warren-Hicks Estimator and Program MARK and better reflects current FWS guidance on mortality studies at solar facilities.
4. Feather Spots – As described in **Section 3.1**, feather spots were problematic in that it is unclear if all feather spots can accurately be attributed to an avian mortality. It is presumed that some proportion of feather spots were the result of avian mortality potentially attributable to project operations or infrastructure; but this proportion is unknown. During collection of data in the fourth quarter 2013, a strict definition of a feather spot mortality was used (≥10 feathers within a $1m^2$ area). We propose giving observers greater discretion in determining whether observed

feathers should be recorded as a likely mortality. This would result in the exclusion of some feather spots where only a few feathers are present with no other evidence of mortality (flesh associated with the feathers, large groups of remiges, feathers from a species not commonly observed in the panel arrays, large numbers of feathers in a concentrated area). With greater discretion, observers would still record feather spot mortalities but could exclude those cases just barely meeting the minimum criteria but not showing any other evidence that an avian mortality has occurred. In cases of any uncertainty, observers would record feather spots as mortalities in order to generate conservative estimates of mortality.

Post-construction Avian Mortality Monitoring Report for the Campo Verde Solar Project

Fourth Quarter 2013

Prepared By:

Heritage Environmental Consultants, LLC

1 Introduction

The Campo Verde Solar Project is a solar photovoltaic (PV) energy generating facility (Solar Energy Facility) and an associated electrical transmission line (Gen-Tie Line) in southern Imperial County, California. The solar project is located on private lands and the gen-tie line is located on private and federal lands managed by the Bureau of Land Management (BLM). These are referred to collectively as the "Project."

A Bird and Bat Conservation Strategy (BBCS) was prepared that addresses activities potentially occurring during construction and operation of the Project (Heritage 2013). The BBCS was reviewed and approved by the U.S. Fish and Wildlife Service (FWS), California Department of Fish and Wildlife (CDFW), and BLM. The purpose of the Campo Verde BBCS was to develop and implement a program to identify and avoid risks to avian and bat species that could result from construction and operation of the Project. The goal of this BBCS was to implement a series of best practices, in order to construct and operate the Project to avoid or reduce risk to birds, bats and their habitats.

The post-construction avian mortality monitoring program was set up to comply with the methodology prescribed in the BBCS (Heritage 2013). The methodology is described in Section 6.1 of the BBCS and was approved by the FWS and CDFW. Quarterly reports documenting results of the monitoring program are required for the first year of program, and annually thereafter. Monitoring began in October 2013 just after completion of construction. This report is the first of four quarterly reports.

1.1 Project Description

The general location of the Project is approximately 7 miles southwest of the city of El Centro, Imperial County, California (**Figure 1**). The Project is south of I-8, west of Drew Road, and northeast and south of the Westside Main Canal. The Project consists of two component parts: (i) the Solar Energy Facility and (ii) an approximately 0.9-mile, 230-kilovolt (kV) aboveground, electrical gen-tie line and associated facilities that electrically connects the Solar Energy Facility on private land with the Imperial Valley Substation (IV Substation) located on federal land managed by the BLM.

The Solar Energy Facility is approximately 1,443 acres in size and uses First Solar PV modules that are generally non-reflective and convert sunlight into direct current (DC) electricity. The DC output of multiple rows of PV modules is collected through one or more combiner boxes and directed to an inverter that converts the DC electricity to alternating current (AC) electricity. From the inverter, the generated energy flows to a transformer where it is stepped up to distribution level voltage (approximately 34.5 kV). Multiple transformers are connected in parallel via 34.5 kV lines to the Project substation, where the power is stepped up to 230 kV. This substation is located at the southern end Solar Energy Facility near Liebert Road. The Gen-Tie Line connects the Project substation to the Imperial Valley Substation approximately 0.9 miles to the south.

The Gen-Tie Line uses double-circuit tubular steel monopole structures. Tower structure heights range from 100 to 135 feet. One side of the double-circuit structures currently supports three two- bundle conductors and one shield wire. Typical overall structure widths are approximately 20 feet.

Project Facilities

2 Methods

Monitoring of the Project was performed in order to document and report avian mortalities and identify areas of concern by tracking both the specific locations where mortalities occur as well as the extent of such mortalities. The monitoring program for the Project is based on the FWS guidance entitled "Monitoring Migratory Bird Take at Solar Power Facilities: An Experimental Approach" (FWS 2012) with modifications, and was approved by FWS.

2.1 Transect Sampling

Sampling transects were established for both the gen-tie line and solar field. For each kilometer of Gen-Tie Line, 300-meter transects were randomly established along the Gen-Tie Line allowing for approximately 30 percent of the Gen-Tie Line to be sampled. Transects were positioned along the centerline of the Gen-Tie Line. For the Campo Verde Solar Energy Facility, transects were also positioned to result in approximately 30-percent coverage of the site with no less than eight transects placed within the solar field itself. Transect selection was systematic randomized. The entire perimeter of the panel arrays was also surveyed during each survey period in addition to the interior transects.

Transects were surveyed for 7 consecutive days each month and each transect was surveyed once daily. Because of the large number of transects, sampling periods were 14-days; the first half of transects were walked for 7- day period and the second half for another 7 day period. One qualified observer walked along the pre-determined transects searching for bird/bat carcasses. When a carcass was observed, a GPS location was recorded at the carcass (for DISTANCE analysis), the species was identified, and information regarding carcass condition per FWS (2012) was recorded using paper datasheets. Once data were collected at a carcass, the observer returned to the pre-determined transect and continued with the survey.

The original protocol stated that each carcass would be marked uniquely and inconspicuously with tape and permanent marker to assess "recapture" rates. However, both the state scientific collection permit (SCP) and the federal special purpose utility permit (SPUT) enabling surveyors to handle carcasses were still being processed during this sampling period so no mark-recapture data was collected. Scavenger removal trials and searcher efficiency trials were also not performed due to the lack of handling permits. Therefore, all estimates presented in this report represent mortality estimates that are uncorrected for observer bias and scavenger removal rates. Future reports will address these biases, once permits are approved by the FWS and CDFW.

2.2 Analysis

Two primary analyses were proposed for mortality estimation. The first analysis used Program DISTANCE to determine the most effective transect width to search for carcasses. Distance models examined a variety of detection functions and used Aikake's Information Criterion (AIC)[1] for model selection.

The second analysis would use Program MARK to estimate total number of mortalities controlling for detection rate, scavenging rate, and proximity to Project components. However, as described above, handling permits have not been approved by either the FWS or CDFW, thus mark-recapture protocols could not be implemented. Future reports will contain a mark-recapture analysis, pending approval of

---

[1] AIC measures the relative quality of a given model by assessing both the model's complexity as well as the model goodness-of-fit to the observed data. Lower AIC values indicate higher quality models. Typically AIC values are compared among several possible models to select the "best" model or models.

handling permits. Alternative analysis packages may be considered (as opposed to Program MARK); see **Section 4.3** for additional discussion of potential statistical analyses.

Project mortality estimates rely on measuring a daily mortality rate that can be used as the basis for all mortality estimates. To calculate the corrected project mortality estimate, we did not count all mortalities observed during day 1 of the 7-day search period under the assumption that the those mortalities represent "bleed through" from the period prior to 24 hours preceding the first search. To accurately generate a rate, all mortalities used for this analysis need to have occurred within the 24 hours preceding discovery. Mortalities observed during the subsequent 6 days were then up-corrected to adjust for time not searched (since the search period captured 6 out of 30 or 31 days each month), producing a time-corrected mortality estimate for each month.

Because taxonomic analyses do not use a rate, but are instead only concerned with the overall breakdown in mortalities, these analyses used all recorded mortality data, including those mortalities observed during day 1 of the 7-day search period. The use of these data from day one assumes that there is not persistence bias for different types of birds. Once scavenger removal trials are approved, this assumption can be tested and analyses will be adjusted if necessary.

3 Results

3.1 Overall Mortalities Observed

Fourth quarter surveys for 2013 were conducted from October 21 – November 3, 2013; November 11-23, 2013; and, December 7-20, 2013. A total of 36 avian mortalities were recorded. Twenty-three (23) of these observed mortalities were recorded as "feather spots" (defined as 10 or more feathers within a 1m^2 area). All feather spots were assumed to be mortalities, though it is unlikely that they all represent a mortality. **Table 1** provides a breakdown of mortalities by sampling period.

Table 1 – Observed Mortalities by Sampling Period

Mortality Type	October (10/21/13 – 11/3/13)	November (11/11/13 – 11/23/13)	December (12/7/13 – 12/20/13)	Q4 2013 TOTAL
Feather Spot Mortalities	6	15	2	23
Non-Feather Spot Mortalities	8	2	3	13
Total Mortalities	*14*	*17*	*5*	*36*

The inclusion of feather spots as observed mortalities is based on standard mortality monitoring protocols, which were largely developed for the wind energy industry. At wind energy facilities, the speed of the spinning blades can result in mortalities that leave very little detectible carcass behind, including only feather spots. Inclusion of feather spots as recorded mortalities at these facilities was intended to conservatively include mortalities caused by blade strikes that might otherwise go unrecorded. Potential bias resulting from the inclusion of feather spots in mortality data can arise from feather spots meeting the definition of a mortality (in this case >10 feathers within 1m^2) but not actually resulting from an avian mortality. This bias can lead to overestimates of mortality rates. This bias is problematic in situations where feathers are commonly deposited in non-mortality related events but get included as incidents of avian morality (e.g. in and around common roost or perch sites, near active nests, etc.). Feather spots may also be caused by predation or attempted-predation events within a survey area. In these cases, the mortality is recorded but the causal relation of that mortality to a project may be misrepresented.

A large proportion of mortalities recorded during the 2013 Q4 surveys were detected as feather spots (over 63% overall and over 88% of mortalities recorded in November). It is unclear if some or all of these feather spots can be accurately attributed to project-related causes, or whether they were actual mortalities. Unlike with wind energy facilities, there are not anticipated project-related mortality hazards that could be expected to result in only feather spot remains. Furthermore, during mortality surveys, biologists routinely observed multiple species perching and roosting on the panels, often times depositing large numbers of feathers. Wintering raptors are also common in the agricultural areas of the Imperial Valley and were routinely observed in and around the panel arrays. Thus, normal perching, roosting, predation and scavenging could account for a significant number of the observed feather spots. Conversely, some of the feather spots were identified as species that would not be expected to naturally occur within the panel arrays and were not previously observed in the interior of the agricultural fields during the pre-construction avian surveys (Heritage 2012). For these reasons, all of the following analyses present results that both include and exclude feather spots to present the full range of possible mortalities. Additional recommendations regarding the use of feather spot data in future surveys can be found in **Section 4.3**.

3.2 Effective Transect Width

DISTANCE analyses were performed using the data pooled across the three-month sampling period and **Tables 2 and 3** present the results of the DISTANCE analysis. It is important to note that none of the models fit the data well and model parameters were constrained to obtain monotonicity[2] in several cases. DISTANCE model fitting issues are discussed in greater detail in **Section 4.3**. The a priori[3] estimate of effective transect width was approximately 7.5 meters (this represents the width of two panel rows measured from the bottom of the panel immediately north of the designated transects to the bottom of the second panel to the south of the transect). Generally, the most likely models were consistent with that assumption. Corrections to the methods used to assess perpendicular distance are expected to improve model fit in future analyses and allow for a more accurate assessment of effective transect width (**Section 4.3**).

Table 2 – Distance Analysis Results – without feather spots

Model Definition	# of Parameters	AIC	ΔAIC	Density (mortalities per hectare)	95% CI	Effective Transect Width (m)
Hazard – Cosine*	2	73.19	0.00	0.150	0.031-0.721	6.24
Uniform – Cosine*	1	73.79	0.61	0.065	0.032-0.132	14.34
Uniform – Polynomial	0	74.19	1.00	0.043	0.077-0.305	22.00
Half Normal – Polynomial	1	74.41	1.22	0.064	0.129-0.369	14.76
Half Normal – Hermit*	1	74.41	1.22	0.064	0.129-0.369	14.76

*Some parameters were constrained to obtain monotonicity.

---

[2] DISTANCE analyses rely on the modeling of a detection function. This detection function models the change in probability of detecting a carcass as the distance from the transect increases. This type of modelling relies on the assumption that the detection function is monotonic. Monotonic means that the probability of detection *only* changes in one direction (decreases) with increasing distance from the transect. If the detection probability goes up and down as distance from the transect increases, then the results violate this assumption of monotonicity. Program DISTANCE automatically constrains certain model parameters to obtain monotonicity but the resulting model may have a poor fit to the observed data.

[3] "A priori" hypotheses are those hypothesis developed based on a theoretical and logical understanding of the system in question and not based on empirical results. That is, a priori hypothesis are those generated before any results have been collected.

Table 3 – Distance Analysis Results – with feather spots

Model Definition	# of Parameters	AIC	ΔAIC	Density (mortalities per hectare)	95% CI	Effective Transect Width
Hazard – Cosine*	2	196.39	0.00	0.394	0.175-0.885	6.75
Uniform – Cosine*	3	199.21	2.82	0.303	0.182-0.506	8.76
Uniform – Polynomial*	5	202.43	6.04	0.318	0.186-0.543	8.37
Half Normal – Polynomial	1	202.90	6.52	0.216	0.139-0.337	12.28
Half Normal – Hermit	1	202.90	6.52	0.216	0.139-0.337	12.28

*Some parameters were constrained to obtain monotonicity.

3.3 Searcher Bias

As described above, permits allowing observers to handle bird carcasses were not in place during these surveys. As such, no searcher bias estimates were generated and overall mortality estimates were not adjusted to reflect searcher bias.

3.4 Scavenger Removal Bias

As described above, permits allowing observers to handle bird carcasses were not in place during these surveys. As such, no scavenger removal trials were completed and overall mortality estimates were not adjusted to reflect scavenger removal bias.

3.5 Corrected Project Mortality Estimate

Results from surveys conducted each month were used to generate discrete mortality estimates for each month surveyed. Monthly and overall project mortality estimates only used data from search days 2-7 (see **Section 2.2**). Monthly mortality estimates were used in order to detect seasonal variations in mortality rates. Also, data are presented to reflect estimates with and without feather spots as discussed earlier. For the remainder of this section, mortality values are presented as “number of mortalities excluding feather spots”/”number of mortalities inclusive of feather spots”.

While results of the DISTANCE analyses were less than conclusive, they were at least consistent with the a priori assumption of a minimum 7.5 meter effective transect width. Transect layout, in consideration of this effective transect width, was designed to sample 30% of the overall PV array area. The time-corrected mortality estimates for each month were again up-corrected to account for the area not surveyed. Since no searcher efficiency or scavenger removal bias corrections were performed, this time- and area-corrected mortality estimate represents the overall monthly project mortality estimate. Mortality estimates were rounded to the nearest whole number. **Table 4** summarizes the corrected mortality estimates by month.

3.5.1 October Mortalities

A total of 6/11 mortalities were detected during days 2-7 of the October surveys. Correcting for time (the 6 day survey period represents approximately 19% of the total days in October) and area surveyed, the overall monthly project mortality estimate for October was 103/189.

3.5.2 November Mortalities

A total of 2/9 mortalities were detected during days 2-7 of the November surveys. Correcting for time (the 6 day survey period represents approximately 20% of the total days in November) and area surveyed, the overall monthly project mortality estimate for November was 33/150.

3.5.3 December Mortalities

A total of 3/5 mortalities were detected during days 2-7 of the December surveys. Correcting for time (the 6 day survey period represents approximately 19% of the total days in December) and area surveyed, the overall monthly project mortality estimate for December was 52/86.

3.5.4 Fourth Quarter 2013 Corrected Mortality Estimates

After applying time and area corrections to the mortality counts for each month the overall project mortality estimate for the fourth quarter of 2013 is 188/426 birds.

Table 4 – Corrected Mortalities by Month

	October		November		December		Q4 Totals	
	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots
Raw Mortality Count (days 2-7)	6	11	2	9	3	5	11	25
Corrected Mortality Estimate	103	189	33	150	52	86	188	426

3.6 Taxonomic Composition of Observed Mortalities

The following analyses use all observed mortalities including those detected on search day 1 since the taxonomic composition is not a rate-dependent analysis (see **Section 3.2**).

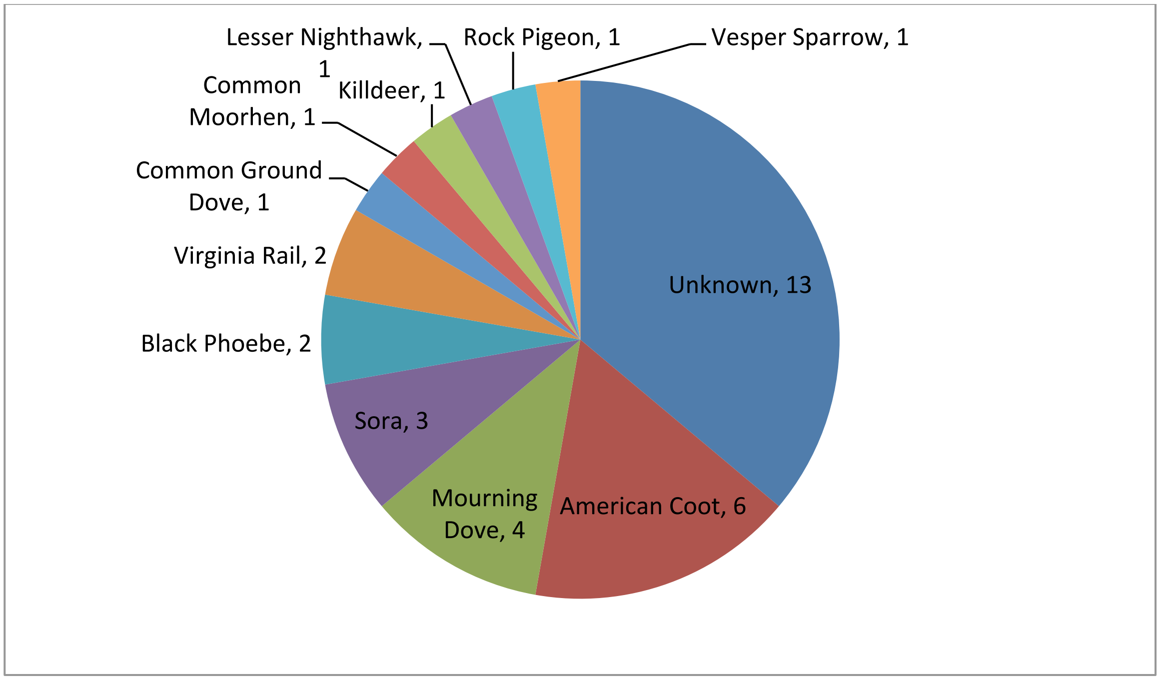
Table 5 – Raw Mortalities by Month (includes data from all search days)

	October		November		December		Q4 Totals	
	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots
Raw Mortality Count (days 1-7)	8	14	2	17	3	5	13	36

3.6.1 Mortalities Including Feather Spots

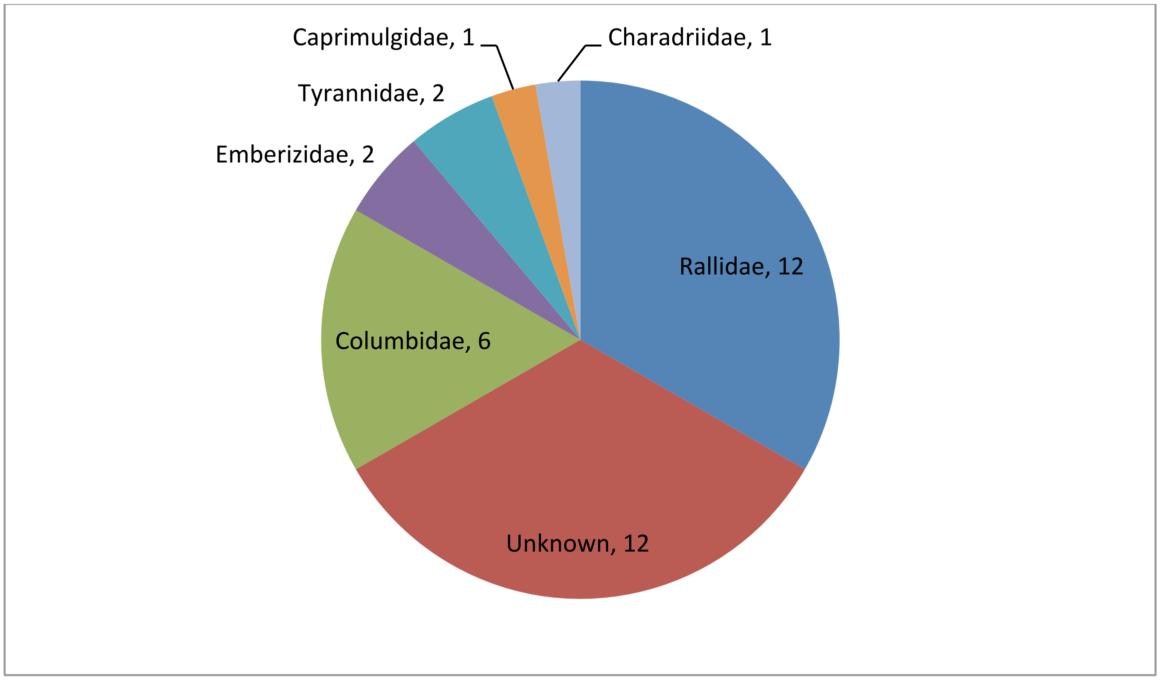
A total of 36 mortalities were observed when feather spots were included in the data set. Thirteen (13) of these mortalities (36%) could not be identified to species. Of the 23 carcasses that could be identified to species, the most commonly observed species were American Coot (*Fulica Americana*; 6 mortalities; 26% of mortalities identified to species level), Mourning Dove (*Zenaida macroura*; 4 mortalities; 18% of mortalities identified to species level), and Sora (*Porzana Carolina*; 3 mortalities; 13% of mortalities identified to species level). **Figure 2** presents the breakdown of observed mortalities by species.

Figure 2 – Mortalities by Species (includes feather spots)



Twenty-four (24) of the 36 observed mortalities could be identified to the family level. Of these 24 mortalities, the families Rallidae (12 mortalities; 50% of mortalities identified to family level), Columbidae (6 mortalities; 25% of mortalities identified to family level), and Emberizidae (2 mortalities; 9% of mortalities identified to family level) were the most commonly observed mortalities. **Figure 3** presents the breakdown of observed mortalities by family.

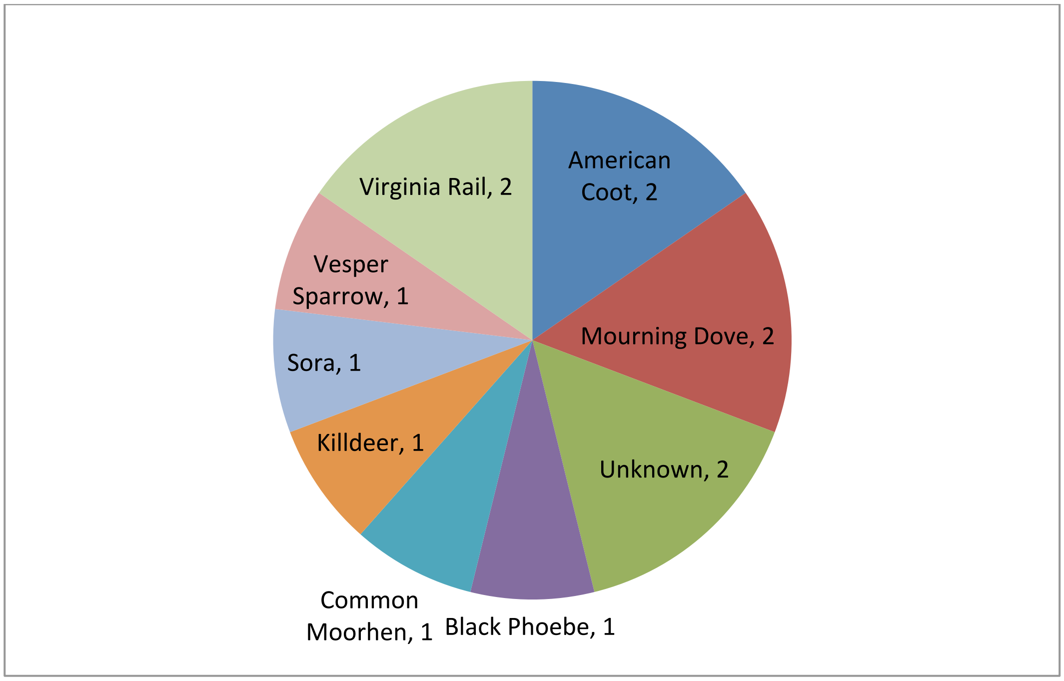
Figure 3 – Mortalities by Family (includes feather spots)



3.6.2 Mortalities Excluding Feather Spots

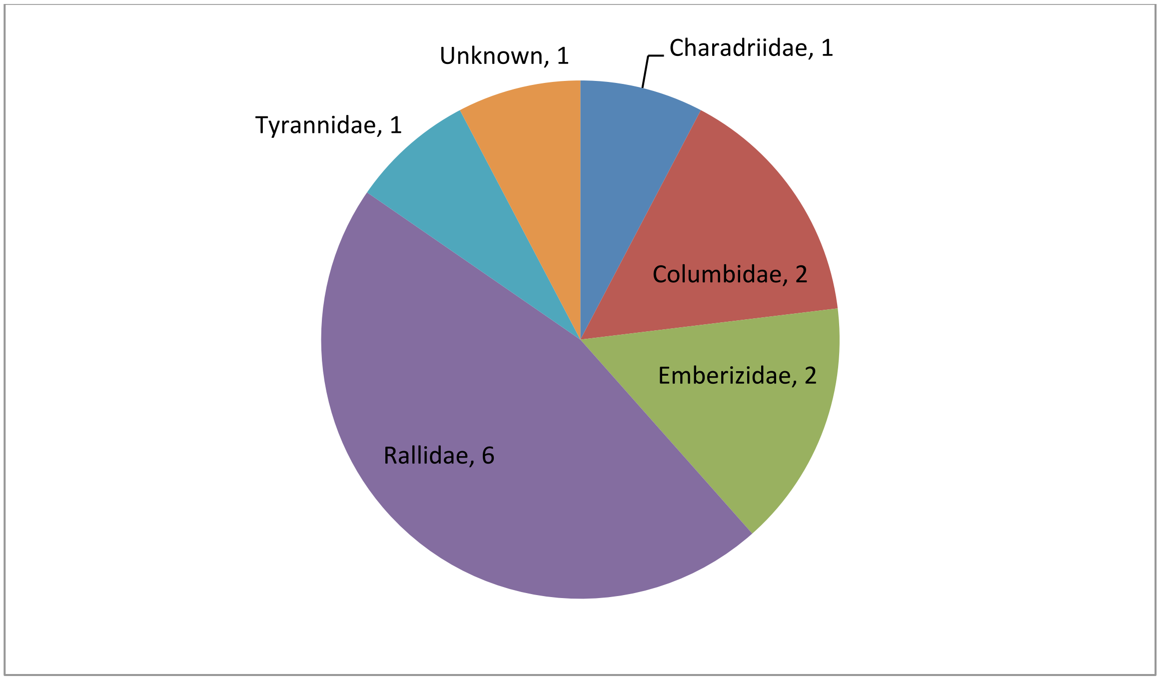
A total of 13 mortalities were observed when feather spots were excluded from the data set. Two (2) of these mortalities (15%) could not be identified to species. Of the 11 carcasses that could be identified to species, the most commonly observed species were American Coot (2 mortalities; 18% of mortalities identified to species level), Mourning Dove (2 mortalities; 18% of mortalities identified to species level), and Virginia Rail (*Rallus limicola*; 2 mortalities; 18% of mortalities identified to species). **Figure 4** presents the breakdown of observed mortalities by species.

Figure 4 - Mortalities by Species (excludes feather spots)



Twelve (12) of the 13 observed mortalities could be identified to the family level. As with the dataset that included feather spots, of these 12 mortalities, the families Rallidae (6 mortalities; 50% of mortalities identified to family level), Columbidae (2 mortalities; 17% of mortalities identified to family level), and Emberizidae (2 mortalities; 17% of mortalities identified to family level) were the most commonly observed mortalities. **Figure 5** presents the breakdown of observed mortalities by family.

Figure 5 – Mortalities by Family (excludes feather spots)



4 Discussion

4.1 Mortality Estimates

Searcher efficiency and scavenger removal trials can only result in up-correcting results (since searchers cannot detect >100% of carcasses and scavengers do not deposit carcasses within a survey area). Because searcher efficiency and scavenger removal trials were not performed during the fourth quarter surveys, the degree of underestimation is unknown. As soon as the Campo Verde Project receives a SPUT permit from FWS and a SCP from CDFW, searcher efficiency and scavenger removal trials will begin. There are no published reports or peer-reviewed articles documenting systematic mortality surveys at a solar photovoltaic facility to compare to the Campo Verde Project.

4.2 Seasonal Variations

A large proportion of the fourth quarter 2013 mortalities were observed in October (55% excluding feather spots; 44% including feather spots). Mortality rates appeared to decline with time. December only accounted for 28% of mortalities (excluding feather spots; 20% when feather spots were included).

4.3 Recommended Methodological Changes

The following changes are recommended to improve survey efficiency and accuracy as well as to improve data collection and analysis.

1. Direct Measurement of Perpendicular Distance – Per the FWS protocol (FWS 2012), a geographic information system was used to measure the perpendicular distance a carcass was located from a transect line. Given the relatively small effective transect width (~7.5m) compared to typical GPS accuracy (~3m), we feel that this method is unlikely to be the most accurate. For subsequent surveys we propose directly measuring the perpendicular distance in the field. The errors in measurement are suspected to have contributed to the lack of monotonicity in the model results.
2. Searcher Efficiency and Scavenger Removal Bias – The results presented in this report are uncorrected for searcher efficiency and scavenger removal. Searcher efficiency at this site is likely very high (near 100%) given the level ground and almost entirely unvegetated environment. As such, the searcher efficiency bias is unlikely to have resulted in a significant underestimate of mortality. However, scavenger removal rates are unknown and could be a source of bias. Numerous potential avian and mammalian scavengers are known to occur in and around the project site. Until scavenger removal trials are performed, the magnitude of this source of bias is unknown. As soon as state and federal permits are approved, these trials will be initiated.
3. Alternative Statistical Analysis Packages – Since the publication of the project BBCS (Heritage 2013), a potentially more robust mortality estimation program has been released for use with the statistical analysis software Program R, called facilityCMR. This program offers several potential advantages over the Warren-Hicks Estimator including analyzing covariance between searcher efficiency and scavenger removal rates and allowing for analysis of carcass condition. We propose using the facilityCMR software in future analyses, as soon as searcher efficiency and scavenger removal trials are permitted. This would be used in lieu of the Warren-Hicks Estimator and Program MARK and better reflects current FWS guidance on mortality studies at solar facilities.
4. Feather Spots – As described in **Section 3.1**, feather spots were problematic in that it is unclear if all feather spots can accurately be attributed to an avian mortality. It is presumed that some proportion of feather spots were the result of avian mortality potentially attributable to project operations or infrastructure; but this proportion is unknown. During collection of data in the fourth quarter 2013, a strict definition of a feather spot mortality was used (≥10 feathers within a $1m^2$ area). We propose giving observers greater discretion in determining whether observed

feathers should be recorded as a likely mortality. This would result in the exclusion of some feather spots where only a few feathers are present with no other evidence of mortality (flesh associated with the feathers, large groups of remiges, feathers from a species not commonly observed in the panel arrays, large numbers of feathers in a concentrated area). With greater discretion, observers would still record feather spot mortalities but could exclude those cases just barely meeting the minimum criteria but not showing any other evidence that an avian mortality has occurred. In cases of any uncertainty, observers would record feather spots as mortalities in order to generate conservative estimates of mortality.

1 Introduction

The Centinela Solar Energy (CSE) Project is a solar photovoltaic (PV) energy generating facility (Solar Energy Facility) located on private lands in southern Imperial County, California.

A Bird and Bat Conservation Strategy (BBCS) was prepared that addresses activities potentially occurring during construction and operation of the Project (Heritage 2012). The BBCS was reviewed and approved by the U.S. Fish and Wildlife Service (FWS), California Department of Fish and Wildlife (CDFW), and the Bureau of Land Management (BLM). The purpose of the Campo Verde BBCS was to develop and implement a program to identify and avoid risks to avian and bat species that could result from construction and operation of the Project. The goal of this BBCS was to implement a series of best practices, in order to construct and operate the Project to avoid or reduce risk to birds, bats and their habitats.

The post-construction avian mortality monitoring program was set up to comply with the methodology prescribed in the BBCS (Heritage 2012). The methodology is described in Section 6.1 of the BBCS and was approved by the FWS and CDFW. Monitoring began in August 2014 just after completion of construction. Monitoring is required for one year following construction. Construction was completed at the end of July 2014. Four quarterly reports documenting results of the monitoring program are required. This report is the first of four quarterly reports.

1.1 Project Description

The CSE Facility (**Figure 1**) is comprised of approximately 2,067 acres of private land, of which approximately 1,861 acres were formerly in active agricultural production. The generation capacity of the CSE Facility is a nominal 275 megawatts alternating current. The CSE Facility uses solar photovoltaic (PV) technology and electronic DC-to-AC power conditioning equipment (inverters) to produce three-phase, 60 Hz, utility-grade electric power directly from sunlight. The PV modules are mounted on racks supported by steel support structures that are anchored or driven into the ground. The PV module racks are a single-axis-tracking system aligned on a north-south axis and that tracks the sun from east to west. The CSE Facility substation is in the southern portion of the CSE Facility site, immediately south of SR 98, approximately mid-way between Pulliam Road and Brockman Road. The purpose of the CSE Facility substation is to aggregate the AC collector lines and increase the voltage of the electricity to 230-kV for connection with the electric grid. The substation includes transformers, medium-voltage and high-voltage circuit breakers, capacitor banks electrical bus work, meters, disconnect switches and an electrical control house. To protect against over-voltages caused by lightning strikes, lightning arresters, overhead shield wires, and lightning masts are installed in the substation.

2 Methods

Monitoring of the project was performed in order to document and report avian mortalities and identify areas of concern by tracking both the specific locations where mortalities occur as well as the extent of such mortalities. The monitoring program for the Project is based on the FWS guidance entitled "Monitoring Migratory Bird Take at Solar Power Facilities: An Experimental Approach" (FWS 2012) with modifications, and was approved by FWS.

2.1 Transect Sampling

Sampling transects were established for the entire solar field and positioned to result in approximately 10-percent coverage of the site with no less than eight transects placed within the solar field itself. Transect selection was systematic randomized. The entire perimeter of the panel arrays was also surveyed during each survey period in addition to the interior transects.

Transects were surveyed for 7 consecutive days each month and each transect was surveyed once daily. One qualified observer walked along the pre-determined transects searching for bird/bat carcasses. When a carcass was observed, a GPS location was recorded at the carcass, the species was identified, the perpendicular distance from the transect to the carcass was measured, and information regarding carcass condition per FWS (2012) was recorded using paper datasheets. Once data were collected at a carcass, the observer returned to the pre-determined transect and continued with the survey.

The original protocol stated that each carcass would be marked uniquely and inconspicuously with tape and permanent marker to assess "recapture" rates. However, both the state scientific collection permit (SCP) and the federal special purpose utility permit (SPUT) enabling surveyors to handle carcasses were still being processed during this sampling period so no mark-recapture data was collected. Scavenger removal trials and searcher efficiency trials were also not performed due to the lack of handling permits. Therefore, all estimates presented in this report represent mortality estimates that are uncorrected for observer bias and scavenger removal rates. Future reports will address these biases, once permits are approved by the FWS and CDFW.

2.2 Analysis

Two primary analyses were proposed for mortality estimation. The first analysis used Program DISTANCE to determine the most effective transect width to search for carcasses. Distance models examined a variety of detection functions and used Aikake's Information Criterion (AIC)[1] for model selection. Models were run using both no truncation as well as 5% upper truncation to remove outliers. Specific model components are discussed in **Section 3.2**.

The second analysis would use Program MARK to estimate total number of mortalities controlling for detection rate, scavenging rate, and proximity to Project components. However, as described above, handling permits have not been approved by either the FWS or CDFW. Thus, mark-recapture protocols could not be implemented. Future reports will contain a mark-recapture analysis, pending approval of handling permits. Alternative analysis packages may be considered (as opposed to Program MARK); see **Section 4.4** for additional discussion of potential statistical analyses.

Project mortality estimates rely on measuring a daily mortality rate that can be used as the basis for all mortality estimates. To calculate the corrected project mortality estimate, we did not count all mortalities observed during day 1 of the 7-day search period under the assumption that the those mortalities represent "bleed through" from the period prior to 24 hours preceding the first search. To accurately generate a rate, all mortalities used for this analysis need to have occurred within the 24 hours preceding discovery. Mortalities observed during the subsequent 6 days were then up-corrected to adjust for time not searched

---

[1] AIC measures the relative quality of a given model by assessing both the model's complexity as well as the model goodness-of-fit to the observed data. Lower AIC values indicate higher quality models. Typically AIC values are compared among several possible models to select the "best" model or models.

(since the search period captured 6 out of 28, 30 or 31 days each month), producing a time-corrected mortality estimate for each month.

Because taxonomic analyses do not use a rate, but are instead only concerned with the overall breakdown in mortalities, these analyses used all recorded mortality data, including those mortalities observed during day 1 of the 7-day search period. The use of these data from day one assumes that there is not persistence bias for different taxa of birds. Once scavenger removal trials are approved, this assumption can be tested and analyses will be adjusted if necessary.

3 Results

3.1 Overall Mortalities Observed

The first three months of surveys for 2014 were conducted from August 23-29, 2014; September 21-27, 2014; and, October 19-25, 2014. A total of 21 avian mortalities were recorded. Eight (8) of these observed mortalities were recorded as "feather spots". **Table 1** provides a breakdown of mortalities by sampling period.

Table 1 – Observed Mortalities by Sampling Period

Mortality Type	August (8/23/14 – 8/29/14)	September (9/21/14 – 9/27/14)	October (10/19/14 – 10/25/14)	Aug.-Oct. 2014 TOTAL
Feather Spot Mortalities	0	2	6	8
Non-Feather Spot Mortalities	6	1	6	13
Total Mortalities	*6*	*3*	*12*	*21*

The inclusion of feather spots as observed mortalities is based on standard mortality monitoring protocols, which were largely developed for the wind energy industry. At wind energy facilities, the speed of the spinning blades can result in mortalities that leave very little detectible carcass behind, including only feather spots. Inclusion of feather spots as recorded mortalities at these facilities was intended to conservatively include mortalities caused by blade strikes that might otherwise go unrecorded. Potential bias resulting from the inclusion of feather spots in mortality data can arise from feather spots meeting the definition of a mortality but not actually resulting from an avian mortality. This bias can lead to overestimates of mortality rates. This bias is problematic in situations where feathers are commonly deposited in non-mortality related events but get included as incidents of avian morality (e.g. in and around common roost or perch sites, near active nests, etc.). Feather spots may also be caused by predation or attempted-predation events within a survey area. Observers used discretion when encountering feather spots to help mitigate this bias. Feather spots that strongly indicated a deposition of feathers that was unrelated to an avian mortality or injury were excluded from the database; in instances where observers were uncertain, the feathers spots were recorded as mortalities in order to be conservative. All of the following analyses present results that both include and exclude feather spots to present the full range of possible mortalities.

3.2 Effective Transect Width

DISTANCE analyses were performed using the data pooled across the three-month sampling period and **Tables 2-5** present the results of the DISTANCE analysis. It is important to note several models had errors likely arising from small sample sizes. These errors included model parameters being constrained to obtain monotonicity[2], parameters at lower bounds[3] and highly correlated parameters. Models were run that included and excluded feather spot as well as models that truncated the data and models that employed no truncation.

---

[2] DISTANCE analyses rely on the modeling of a detection function. This detection function models the change in probability of detecting a carcass as the distance from the transect increases. This type of modelling relies on the assumption that the detection function is monotonic. Monotonic means that the probability of detection *only* changes in one direction (decreases) with increasing distance from the transect. If the detection probability goes up and down as distance from the transect increases, then the results violate this assumption of monotonicity. Program DISTANCE automatically constrains certain model parameters to obtain monotonicity but the resulting model may have a poor fit to the observed data.

[3] Similar error to footnote 2.

The a priori[4] estimate of effective transect width was approximately 8.4 meters (this represents the width of two panel rows measured from the pier of the panel immediately east of the designated transects to the pier of the second panel to the west of the transect). Generally, the most likely models were consistent with or exceeded that assumption. Sample sizes were small for all models run this quarter and model results should be used with some caution. Many of the errors encountered are likely the result of small sample sizes.

[4] "A priori" hypotheses are those hypothesis developed based on a theoretical and logical understanding of the system in question and not based on empirical results. That is, a priori hypothesis are those generated before any results have been collected.

3.3 Searcher Bias

As described above, permits allowing observers to handle bird carcasses had not been issued at the time of these surveys. As such, no searcher bias estimates were generated and overall mortality estimates were not adjusted to reflect searcher bias.

3.4 Scavenger Removal Bias

As described above, permits allowing observers to handle bird carcasses had not been issued at the time of these surveys. As such, no scavenger removal trials were completed and overall mortality estimates were not adjusted to reflect scavenger removal bias.

3.5 Corrected Project Mortality Estimate

Results from surveys conducted each month were used to generate discrete mortality estimates for each month surveyed. Monthly and overall project mortality estimates only used data from search days 2-7 (see **Section 2.2**). Monthly mortality estimates were used in order to detect seasonal variations in mortality rates. Also, data are presented to reflect estimates with and without feather spots, as discussed earlier. For the remainder of this section, mortality values are presented as "number of mortalities excluding feather spots"/"number of mortalities inclusive of feather spots".

While results of the DISTANCE analyses were less than conclusive, they were at least consistent with the a priori assumption of a minimum 8.4-meter effective transect width. Transect layout, in consideration of this assumed effective transect width, was designed to sample 10% of the overall PV array area. The time-corrected mortality estimates for each month were again up-corrected to account for the area not surveyed. Since no searcher efficiency or scavenger removal bias corrections were performed, this time- and area-corrected mortality estimate represents the overall monthly project mortality estimate. Mortality estimates were rounded to the nearest whole number. **Table 6** summarizes the corrected mortality estimates by month.

3.5.1 August Mortalities

A total of 6/6 mortalities were detected during days 2-7 of the August surveys. Correcting for time (the 6 day survey period represents approximately 19% of the total days in August) and area surveyed, the overall monthly project mortality estimate for August was 310/310.

3.5.2 September Mortalities

A total of 0/0 mortalities were detected during days 2-7 of the September surveys. Therefore, the overall monthly project mortality estimate for September was 0/0.

3.5.3 October Mortalities

A total of 3/7 mortalities were detected during days 2-7 of the October surveys. Correcting for time (the 6 day survey period represents approximately 19% of the total days in October) and area surveyed, the overall monthly project mortality estimate for June was 155/362.

3.5.4 August - October 2014 Corrected Mortality Estimates

After applying time and area corrections to the mortality counts for each month the overall project mortality estimate for the period August to October of 2014 is 465/672.

Table 6 – Corrected Mortalities by Month

	August		September		October		Aug.-Oct. Totals	
	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots
Raw Mortality Count (days 2-7)	6	6	0	0	3	7	9	13
Corrected Mortality Estimate	310	310	0	0	155	362	465	672

3.6 Taxonomic Composition of Observed Mortalities

The following analyses use all observed mortalities including those detected on search day 1 since the taxonomic composition is not a rate-dependent analysis (see **Section 2.2**).

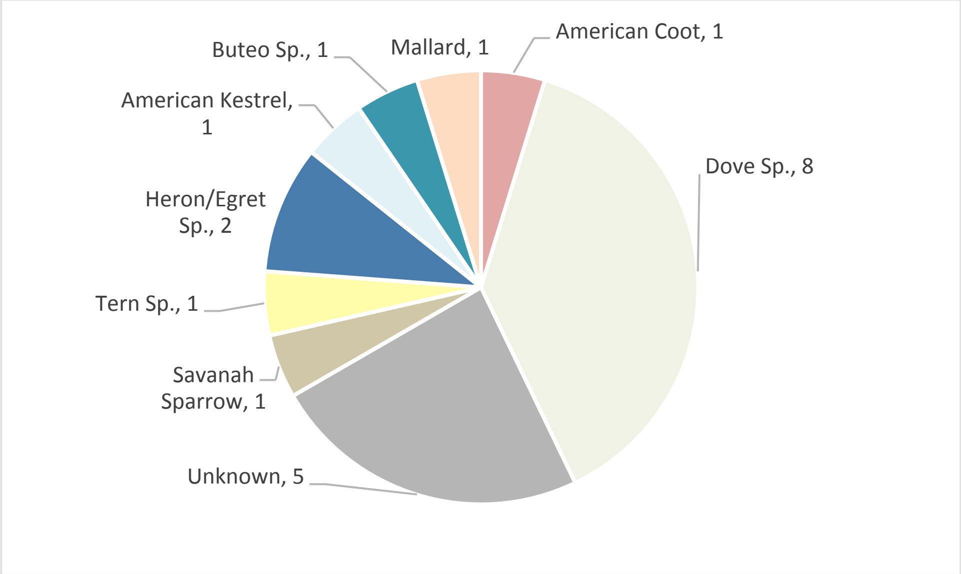
Table 7 – Raw Mortalities by Month (includes data from all search days)

	August		September		October		Aug.-Oct. Totals	
	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots
Raw Mortality Count (days 1-7)	6	6	1	3	6	12	13	21

3.6.1 Mortalities Including Feather Spots

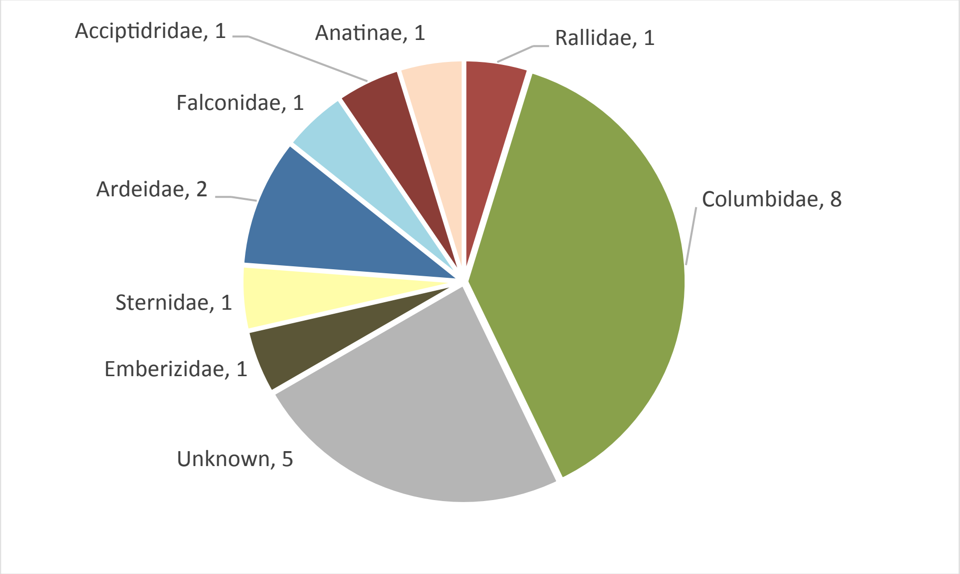
A total of 21 mortalities were observed when feather spots were included in the data set. Eleven (11) of these mortalities (52%) could not be identified to species. The 10 carcasses that could be identified to species each represents a unique species – no single species was more common than any others. **Figure 2** presents the breakdown of observed mortalities by species.

Figure 2 – Mortalities by Species (includes feather spots)



Sixteen (16) of the 21 observed mortalities could be identified to the family level. Of these 16 mortalities, the families Columbidae (8 mortalities; 50% of mortalities identified to family level) and Ardeidae (2 mortalities; 13% of mortalities identified to family level) were the most commonly observed mortalities. **Figure 3** presents the breakdown of observed mortalities by family.

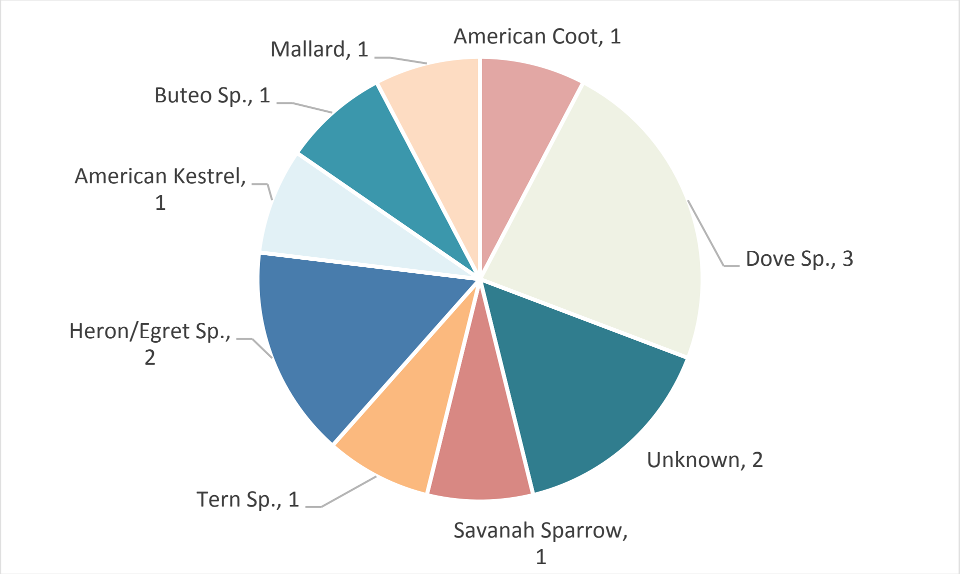
Figure 3 – Mortalities by Family (includes feather spots)



3.6.2 Mortalities Excluding Feather Spots

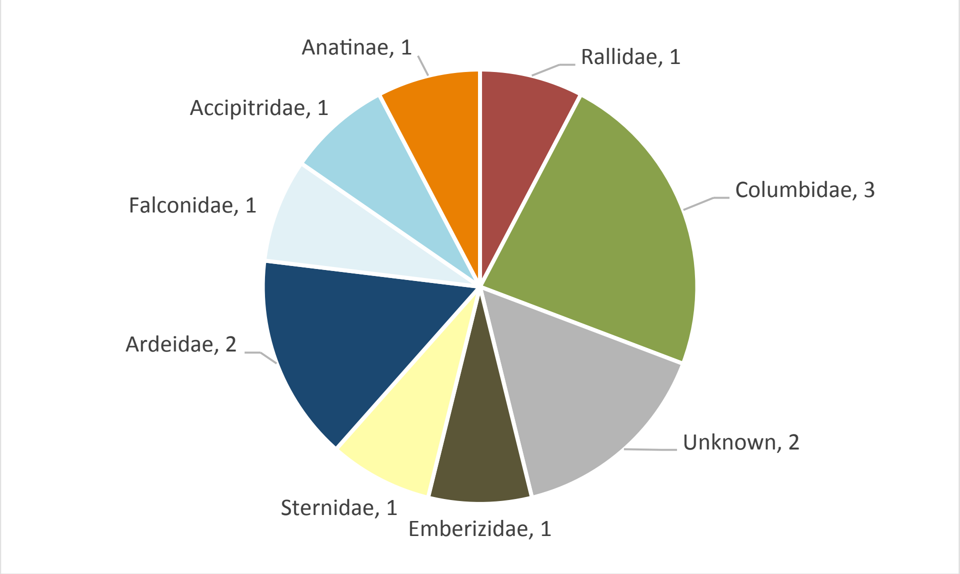
A total of 13 mortalities were observed when feather spots were excluded from the data set. Five (5) of these mortalities (38%) could be identified to species. The 8 carcasses that could be identified to species each represents a unique species – no single species was more common than any others. **Figure 4** presents the breakdown of observed mortalities by species.

Figure 4 - Mortalities by Species (excludes feather spots)



Eleven (11) of the 13 observed mortalities could be identified to the family level. Of these mortalities, the families Columbidae (3 mortalities; 27% of mortalities identified to family level) and Ardeidae (2 mortalities; 18% of mortalities identified to family level) were the most commonly observed. **Figure 5** presents the breakdown of observed mortalities by family.

Figure 5 – Mortalities by Family (excludes feather spots)



4 Discussion

4.1 Mortality Estimates

Searcher efficiency and scavenger removal trials can only result in up-correcting results (since searchers cannot detect >100% of carcasses and scavengers are unlikely to deposit carcasses within a survey area). Because searcher efficiency and scavenger removal trials were not performed during the second quarter surveys, the degree of underestimation is unknown. As soon as the Centinela Solar Energy Project receives a SPUT permit from FWS and a SCP from CDFW, searcher efficiency and scavenger removal trials will begin.

4.2 Seasonal Variations

There was strong variation in estimated mortality rates from month to month. The September estimated mortality rate was 0, whereas August and October estimated mortality rates were significantly higher (310/310 and 155/362, respectively). It should be noted that the sample size of observed mortalities was low this quarter (especially relative to the magnitude of the correction factors), making these types of analyses difficult to achieve high confidence levels.

4.3 Recommended Methodological Changes

The following changes are recommended to improve survey efficiency and accuracy as well as to improve data collection and analysis.

1. Searcher Efficiency and Scavenger Removal Bias – The results presented in this report are uncorrected for searcher efficiency and scavenger removal. Searcher efficiency at this site is likely very high (near 100%) given the level ground and almost entirely unvegetated environment. As such, the searcher efficiency bias is unlikely to have resulted in a significant underestimate of mortality. However, scavenger removal rates are unknown and could be a source of bias. Numerous potential avian and mammalian scavengers are known to occur in and around the project site. Until scavenger removal trials are performed, the magnitude of this source of bias is unknown. As soon as state and federal permits are approved, these trials will be initiated.
2. Alternative Statistical Analysis Packages – Since the publication of the project BBCS (Heritage 2012), a potentially more robust mortality estimation program has been released for use with the statistical analysis software Program R, called *facilityCMR*. This program offers several potential advantages over the Warren-Hicks Estimator including analyzing covariance between searcher efficiency and scavenger removal rates and allowing for analysis of carcass condition. We propose using the *facilityCMR* software in future analyses, as soon as searcher efficiency and scavenger removal trials are permitted. This would be used in lieu of the Warren-Hicks Estimator and Program MARK and better reflects current FWS guidance on mortality studies at solar facilities.

Post-construction Avian Mortality Monitoring Report
Centinela Solar Energy Project

Third Quarterly Report (February-March-April, 2015)

Prepared By:

Heritage Environmental Consultants, LLC

Table of Contents

1 Introduction

The Centinela Solar Energy (CSE) Project is a solar photovoltaic (PV) energy generating facility (Solar Energy Facility) located on private lands in southern Imperial County, California.

A Bird and Bat Conservation Strategy (BBCS) was prepared that addresses activities potentially occurring during construction and operation of the Project (Heritage 2012). The BBCS was reviewed and approved by the U.S. Fish and Wildlife Service (FWS), California Department of Fish and Wildlife (CDFW), and the Bureau of Land Management (BLM). The purpose of the Centinela BBCS was to develop and implement a program to identify and avoid risks to avian and bat species that could result from construction and operation of the Project. The goal of this BBCS was to implement a series of best practices, in order to construct and operate the Project to avoid or reduce risk to birds, bats and their habitats.

The post-construction avian mortality monitoring program was set up to comply with the methodology prescribed in the BBCS (Heritage 2012). The methodology is described in Section 6.1 of the BBCS and was approved by the FWS and CDFW. Monitoring began in August 2014 just after completion of construction. Monitoring is required for one year following construction. Construction was completed at the end of July 2014. Four quarterly reports documenting results of the monitoring program are required. This report is the third of four quarterly reports.

1.1 Project Description

The CSE Facility (**Figure 1**) is comprised of approximately 2,067 acres of private land, of which approximately 1,861 acres were formerly in active agricultural production. The generation capacity of the CSE Facility is a nominal 275 megawatts alternating current. The CSE Facility uses solar photovoltaic (PV) technology and electronic DC-to-AC power conditioning equipment (inverters) to produce three-phase, 60 Hz, utility-grade electric power directly from sunlight. The PV modules are mounted on racks supported by steel support structures that are anchored or driven into the ground. The PV module racks are a single-axis-tracking system aligned on a north-south axis and that tracks the sun from east to west. The CSE Facility substation is in the southern portion of the CSE Facility site, immediately south of SR 98, approximately mid-way between Pulliam Road and Brockman Road. The purpose of the CSE Facility substation is to aggregate the AC collector lines and increase the voltage of the electricity to 230-kV for connection with the electric grid. The substation includes transformers, medium-voltage and high-voltage circuit breakers, capacitor banks electrical bus work, meters, disconnect switches and an electrical control house. To protect against over-voltages caused by lightning strikes, lightning arresters, overhead shield wires, and lightning masts are installed in the substation.

2 Methods

Monitoring of the project was performed in order to document and report avian mortalities and identify areas of concern by tracking both the specific locations where mortalities occur as well as the extent of such mortalities. The monitoring program for the Project is based on the FWS guidance entitled "Monitoring Migratory Bird Take at Solar Power Facilities: An Experimental Approach" (FWS 2012) with modifications, and was approved by FWS.

2.1 Transect Sampling

Sampling transects were established for the entire solar field and positioned to result in approximately 10-percent coverage of the site with no less than eight transects placed within the solar field itself. Transect selection was systematic randomized. The entire perimeter of the panel arrays was also surveyed during each survey period in addition to the interior transects.

Transects were surveyed for 7 consecutive days each month and each transect was surveyed once daily. One qualified observer walked along the pre-determined transects searching for bird/bat carcasses. When a carcass was observed, a GPS location was recorded at the carcass, the species was identified, the perpendicular distance from the transect to the carcass was measured, and information regarding carcass condition per FWS (2012) was recorded using paper datasheets. Once data were collected at a carcass, the observer returned to the pre-determined transect and continued with the survey.

The original protocol stated that each carcass would be marked uniquely and inconspicuously with tape and permanent marker to assess "recapture" rates. However, both the state scientific collection permit (SCP) and the federal special purpose utility permit (SPUT) enabling surveyors to handle carcasses were still being processed during this sampling period so no mark-recapture data was collected. Scavenger removal trials and searcher efficiency trials were also not performed due to the lack of handling permits. Therefore, all estimates presented in this report represent mortality estimates that are uncorrected for observer bias and scavenger removal rates. Future reports will address these biases, once permits are approved by the FWS and CDFW.

2.2 Analysis

Two primary analyses were proposed for mortality estimation. The first analysis used Program DISTANCE to determine the most effective transect width to search for carcasses. Distance models examined a variety of detection functions and used Aikake's Information Criterion (AIC)[1] for model selection. Models were run using both no truncation as well as 5% upper truncation to remove outliers. Specific model components are discussed in **Section 3.2**.

The second analysis would use Program MARK to estimate total number of mortalities controlling for detection rate, scavenging rate, and proximity to Project components. However, as described above, handling permits have not been approved by either the FWS or CDFW. Thus, mark-recapture protocols could not be implemented. Future reports will contain a mark-recapture analysis, pending approval of handling permits. Alternative analysis packages may be considered (as opposed to Program MARK); see **Section 4.4** for additional discussion of potential statistical analyses.

Project mortality estimates rely on measuring a daily mortality rate that can be used as the basis for all mortality estimates. To calculate the corrected project mortality estimate, we did not count all mortalities observed during day 1 of the 7-day search period under the assumption that some of those mortalities represent "bleed through" from the period prior to 24 hours preceding the first search. To accurately generate a rate, all mortalities used for this analysis need to have occurred within the 24 hours preceding discovery. Mortalities observed during the subsequent 6 days were then up-corrected to adjust for time

---

[1] AIC measures the relative quality of a given model by assessing both the model's complexity as well as the model goodness-of-fit to the observed data. Lower AIC values indicate higher quality models. Typically AIC values are compared among several possible models to select the "best" model or models.

not searched (since the search period captured 6 out of 28, 30 or 31 days each month), producing a time-corrected mortality estimate for each month.

Because taxonomic analyses do not use a rate, but are instead only concerned with the overall breakdown in mortalities, these analyses used all recorded mortality data, including those mortalities observed during day 1 of the 7-day search period. The use of these data from day one assumes that there is not persistence bias for different taxa of birds. Once scavenger removal trials are approved, this assumption can be tested and analyses will be adjusted if necessary.

3 Results

3.1 Overall Mortalities Observed

The three months of surveys were conducted from February 18-24, 2015; March 18-24, 2015; and, April 22-28, 2015. A total of 13 avian mortalities were recorded. Five (5) of these observed mortalities were recorded as "feather spots". **Table 1** provides a breakdown of mortalities by sampling period.

Table 1 – Observed Mortalities by Sampling Period

Mortality Type	February (2/18/15 – 2/24/15)	March (2/18/15 – 2/24/15)	April (4/22/15 – 4/28/15)	Feb.-Apr. 2015 TOTAL
Feather Spot Mortalities	1	1	3	5
Non-Feather Spot Mortalities	3	2	3	8
Total Mortalities	*4*	*3*	*6*	*13*

The inclusion of feather spots as observed mortalities is based on standard mortality monitoring protocols, which were largely developed for the wind energy industry. At wind energy facilities, the speed of the spinning blades can result in mortalities that leave very little detectible carcass behind, including only feather spots. Inclusion of feather spots as recorded mortalities at these facilities was intended to conservatively include mortalities caused by blade strikes that might otherwise go unrecorded. Potential bias resulting from the inclusion of feather spots in mortality data can arise from feather spots meeting the definition of a mortality but not actually resulting from an avian mortality. This bias can lead to overestimates of mortality rates. This bias is problematic in situations where feathers are commonly deposited in non-mortality related events but get included as incidents of avian morality (e.g. in and around common roost or perch sites, near active nests, etc.). Feather spots may also be caused by predation or attempted-predation events within a survey area. Observers used discretion when encountering feather spots to help mitigate this bias. Feather spots that strongly indicated a deposition of feathers that was unrelated to an avian mortality or injury were excluded from the database; in instances where observers were uncertain, the feathers spots were recorded as mortalities in order to be conservative. All of the following analyses present results that both include and exclude feather spots to present the full range of possible mortalities.

3.2 Effective Transect Width

DISTANCE analyses were performed using the data pooled across the three-month sampling period and **Tables 2-5** present the results of the DISTANCE analysis. It is important to note several models had errors likely arising from small sample sizes. These errors included model parameters being constrained to obtain monotonicity[2], parameters at lower bounds[3] and highly correlated parameters. Models were run that included and excluded feather spot as well as models that truncated the data and models that employed no truncation.

---

[2] DISTANCE analyses rely on the modeling of a detection function. This detection function models the change in probability of detecting a carcass as the distance from the transect increases. This type of modelling relies on the assumption that the detection function is monotonic. Monotonic means that the probability of detection *only* changes in one direction (decreases) with increasing distance from the transect. If the detection probability goes up and down as distance from the transect increases, then the results violate this assumption of monotonicity. Program DISTANCE automatically constrains certain model parameters to obtain monotonicity but the resulting model may have a poor fit to the observed data.

[3] Similar error to footnote 2.

The a priori[4] estimate of effective transect width was approximately 8.4 meters (this represents the width of two panel rows measured from the pier of the panel immediately east of the designated transects to the pier of the second panel to the west of the transect). Generally, the most likely models were consistent with or exceeded that assumption. Sample sizes were small for all models run this quarter and model results should be used with caution. Many of the errors encountered are likely the result of very small sample sizes.

---

[4] "A priori" hypotheses are those hypothesis developed based on a theoretical and logical understanding of the system in question and not based on empirical results. That is, a priori hypothesis are those generated before any results have been collected.

3.3 Searcher Bias

As described above, permits allowing observers to handle bird carcasses had not been issued at the time of these surveys. As such, no searcher bias estimates were generated and overall mortality estimates were not adjusted to reflect searcher bias.

3.4 Scavenger Removal Bias

As described above, permits allowing observers to handle bird carcasses had not been issued at the time of these surveys. As such, no scavenger removal trials were completed and overall mortality estimates were not adjusted to reflect scavenger removal bias.

3.5 Corrected Project Mortality Estimate

Results from surveys conducted each month were used to generate discrete mortality estimates for each month surveyed. Monthly and overall project mortality estimates only used data from search days 2-7 (see **Section 2.2**). Monthly mortality estimates were used in order to detect seasonal variations in mortality rates. Also, data are presented to reflect estimates with and without feather spots, as discussed earlier. For the remainder of this section, mortality values are presented as "number of mortalities excluding feather spots"/"number of mortalities inclusive of feather spots".

While results of the DISTANCE analyses were less than conclusive, they were at least consistent with the a priori assumption of a minimum 8.4-meter effective transect width. Transect layout, in consideration of this assumed effective transect width, was designed to sample 10% of the overall PV array area. The time-corrected mortality estimates for each month were again up-corrected to account for the area not surveyed. Since no searcher efficiency or scavenger removal bias corrections were performed, this time- and area-corrected mortality estimate represents the overall monthly project mortality estimate. Mortality estimates were rounded to the nearest whole number. **Table 6** summarizes the corrected mortality estimates by month.

3.5.1 February Mortalities

A total of 1/1 mortalities were detected during days 2-7 of the February surveys. Correcting for time (the 6 day survey period represents approximately 21% of the total days in February) and area surveyed, the overall monthly project mortality estimate for February was 47/47.

3.5.2 March Mortalities

A total of 1/1 mortalities were detected during days 2-7 of the March surveys. Correcting for time (the 6 day survey period represents approximately 19% of the total days in March) and area surveyed, the overall monthly project mortality estimate for March was 52/52.

3.5.3 April Mortalities

A total of 2/4 mortalities were detected during days 2-7 of the April surveys. Correcting for time (the 6 day survey period represents approximately 20% of the total days in April) and area surveyed, the overall monthly project mortality estimate for January was 100/200.

3.5.4 February – April 2015 Corrected Mortality Estimates

After applying time and area corrections to the mortality counts for each month the overall project mortality estimate for the period February to January of 2015 is 198/298.

Table 6 – Corrected Mortalities by Month

	November		December		January		Nov-Jan. Totals	
	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots
Raw Mortality Count (days 2-7)	1	1	1	1	2	4	4	6
Corrected Mortality Estimate	47	47	52	52	100	200	198	298

3.6 Taxonomic Composition of Observed Mortalities

The following analyses use all observed mortalities including those detected on search day 1 since the taxonomic composition is not a rate-dependent analysis (see **Section 2.2**).

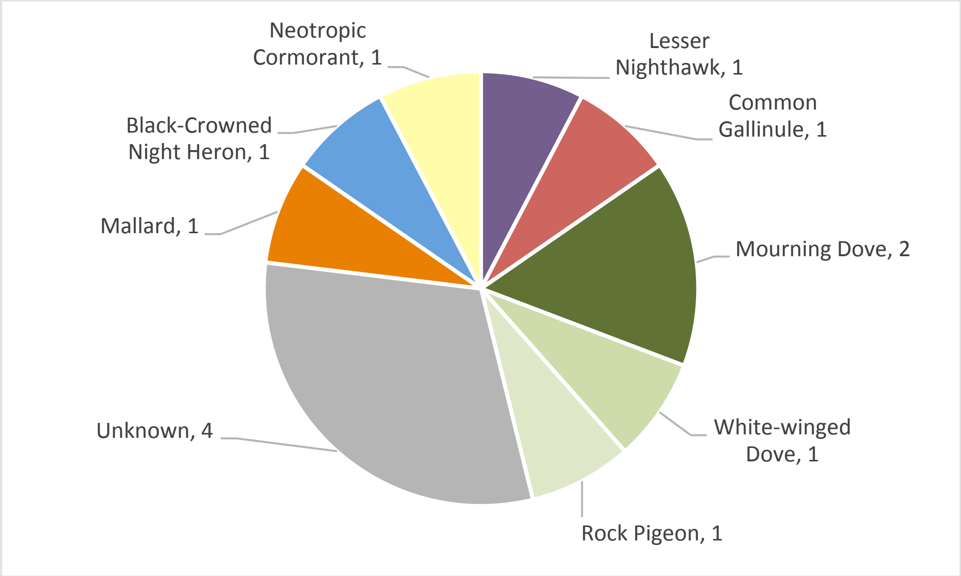
Table 7 – Raw Mortalities by Month (includes data from all search days)

	February		March		April		Feb.-Apr. Totals	
	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots
Raw Mortality Count (days 1-7)	3	4	2	3	3	6	8	13

3.6.1 Mortalities Including Feather Spots

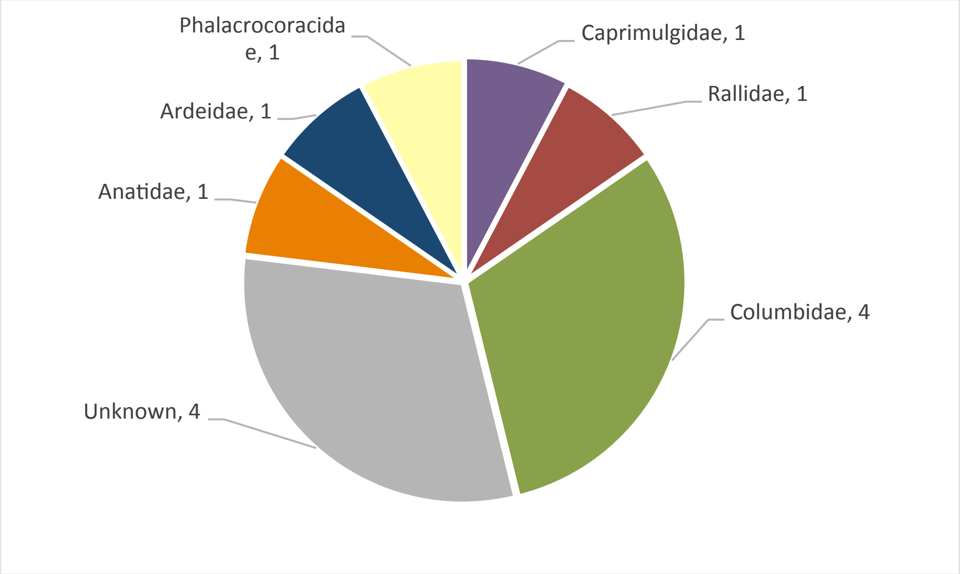
A total of 13 mortalities were observed when feather spots were included in the data set. Four (4) of these mortalities (31%) could not be identified to species. Of the 9 carcasses that could be identified to species, the most commonly observed species was Mourning Dove (*Zenaida macroura*; 2 mortalities; 22% of mortalities identified to species); all other mortalities represented unique species. **Figure 2** presents the breakdown of observed mortalities by species.

Figure 2 – Mortalities by Species (includes feather spots)



Nine (9) of the 13 observed mortalities could be identified to the family level. Of these 9 mortalities, the family Columbidae (4 mortalities; 44% of mortalities identified to family level) was the most commonly observed mortalities. **Figure 3** presents the breakdown of observed mortalities by family.

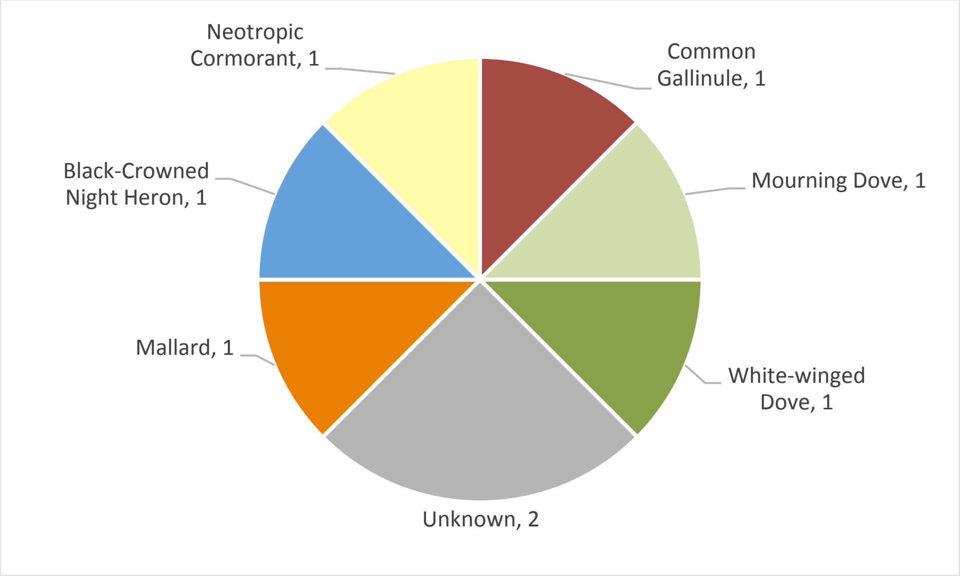
Figure 3 – Mortalities by Family (includes feather spots)



3.6.2 Mortalities Excluding Feather Spots

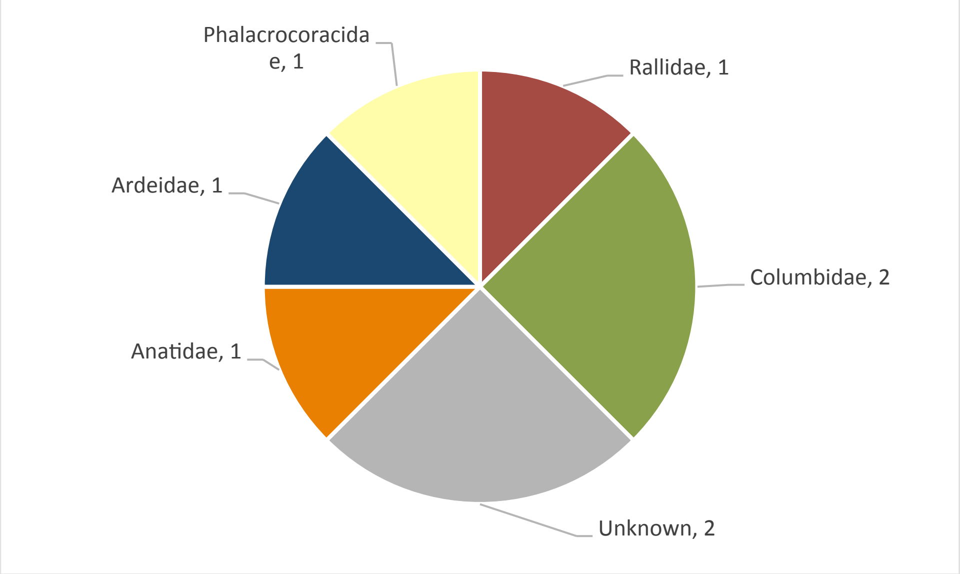
A total of eight (8) mortalities were observed when feather spots were excluded from the data set. Six (6) of these mortalities (75%) could be identified to species. Each of the 6 carcasses that could be identified to species represented the only mortality recorded for that species. **Figure 4** presents the breakdown of observed mortalities by species.

Figure 4 - Mortalities by Species (excludes feather spots)



Six (6) of the 8 observed mortalities could be identified to the family level. Of these mortalities, the family Columbidae (2 mortalities; 25% of mortalities identified to family level) was the most commonly observed. **Figure 5** presents the breakdown of observed mortalities by family.

Figure 5 – Mortalities by Family (excludes feather spots)



4 Discussion

4.1 Mortality Estimates

Searcher efficiency and scavenger removal trials can only result in up-correcting results (since searchers cannot detect >100% of carcasses and scavengers are unlikely to deposit carcasses within a survey area). Because searcher efficiency and scavenger removal trials were not performed during the second quarter surveys, the degree of underestimation is unknown. As soon as the Centinela Solar Energy Project receives a SPUT permit from FWS and a SCP from CDFW, searcher efficiency and scavenger removal trials will begin.

4.2 Seasonal Variations

There was some variation in estimated mortality rates from month to month, especially within the dataset excluding feather-spot mortalities. The February and March estimated mortality rates were 47/47 and 52/52, respectively; whereas the April estimated mortality rate was appreciably higher (100/200). It should be noted that the sample size of observed mortalities was fairly low this quarter (especially relative to the magnitude of the correction factors), making these types of analyses difficult to achieve with high confidence levels.

4.3 Recommended Methodological Changes

The following changes are recommended to improve survey efficiency and accuracy as well as to improve data collection and analysis.

1. Searcher Efficiency and Scavenger Removal Bias – The results presented in this report are uncorrected for searcher efficiency and scavenger removal. Searcher efficiency at this site is likely very high (near 100%) given the level ground and almost entirely unvegetated environment. As such, the searcher efficiency bias is unlikely to have resulted in a significant underestimate of mortality. However, scavenger removal rates are unknown and could be a source of bias. Numerous potential avian and mammalian scavengers are known to occur in and around the project site. Until scavenger removal trials are performed, the magnitude of this source of bias is unknown. As soon as state and federal permits are approved, these trials will be initiated.
2. Alternative Statistical Analysis Packages – Since the publication of the project BBCS (Heritage 2012), a potentially more robust mortality estimation program has been released for use with the statistical analysis software Program R, called *facilityCMR*. This program offers several potential advantages over the Warren-Hicks Estimator including analyzing covariance between searcher efficiency and scavenger removal rates and allowing for analysis of carcass condition. We propose using the *facilityCMR* software in future analyses, as soon as searcher efficiency and scavenger removal trials are permitted. This would be used in lieu of the Warren-Hicks Estimator and Program MARK and better reflects current FWS guidance on mortality studies at solar facilities.

Post-construction Avian Mortality Monitoring Report Centinela Solar Energy Project

---

Second Quarterly Report (November-December 2014,-January 2015)

Prepared By:

Heritage Environmental Consultants, LLC

Table of Contents

1 Introduction

The Centinela Solar Energy (CSE) Project is a solar photovoltaic (PV) energy generating facility (Solar Energy Facility) located on private lands in southern Imperial County, California.

A Bird and Bat Conservation Strategy (BBCS) was prepared that addresses activities potentially occurring during construction and operation of the Project (Heritage 2012). The BBCS was reviewed and approved by the U.S. Fish and Wildlife Service (FWS), California Department of Fish and Wildlife (CDFW), and the Bureau of Land Management (BLM). The purpose of the Centinela BBCS was to develop and implement a program to identify and avoid risks to avian and bat species that could result from construction and operation of the Project. The goal of this BBCS was to implement a series of best practices, in order to construct and operate the Project to avoid or reduce risk to birds, bats and their habitats.

The post-construction avian mortality monitoring program was set up to comply with the methodology prescribed in the BBCS (Heritage 2012). The methodology is described in Section 6.1 of the BBCS and was approved by the FWS and CDFW. Monitoring began in August 2014 just after completion of construction. Monitoring is required for one year following construction. Construction was completed at the end of July 2014. Four quarterly reports documenting results of the monitoring program are required. This report is the second of four quarterly reports.

1.1 Project Description

The CSE Facility (**Figure 1**) is comprised of approximately 2,067 acres of private land, of which approximately 1,861 acres were formerly in active agricultural production. The generation capacity of the CSE Facility is a nominal 275 megawatts alternating current. The CSE Facility uses solar photovoltaic (PV) technology and electronic DC-to-AC power conditioning equipment (inverters) to produce three-phase, 60 Hz, utility-grade electric power directly from sunlight. The PV modules are mounted on racks supported by steel support structures that are anchored or driven into the ground. The PV module racks are a single-axis-tracking system aligned on a north-south axis and that tracks the sun from east to west. The CSE Facility substation is in the southern portion of the CSE Facility site, immediately south of SR 98, approximately mid-way between Pulliam Road and Brockman Road. The purpose of the CSE Facility substation is to aggregate the AC collector lines and increase the voltage of the electricity to 230-kV for connection with the electric grid. The substation includes transformers, medium-voltage and high-voltage circuit breakers, capacitor banks electrical bus work, meters, disconnect switches and an electrical control house. To protect against over-voltages caused by lightning strikes, lightning arresters, overhead shield wires, and lightning masts are installed in the substation.

2 Methods

Monitoring of the project was performed in order to document and report avian mortalities and identify areas of concern by tracking both the specific locations where mortalities occur as well as the extent of such mortalities. The monitoring program for the Project is based on the FWS guidance entitled "Monitoring Migratory Bird Take at Solar Power Facilities: An Experimental Approach" (FWS 2012) with modifications, and was approved by FWS.

2.1 Transect Sampling

Sampling transects were established for the entire solar field and positioned to result in approximately 10-percent coverage of the site with no less than eight transects placed within the solar field itself. Transect selection was systematic randomized. The entire perimeter of the panel arrays was also surveyed during each survey period in addition to the interior transects.

Transects were surveyed for 7 consecutive days each month and each transect was surveyed once daily. One qualified observer walked along the pre-determined transects searching for bird/bat carcasses. When a carcass was observed, a GPS location was recorded at the carcass, the species was identified, the perpendicular distance from the transect to the carcass was measured, and information regarding carcass condition per FWS (2012) was recorded using paper datasheets. Once data were collected at a carcass, the observer returned to the pre-determined transect and continued with the survey.

The original protocol stated that each carcass would be marked uniquely and inconspicuously with tape and permanent marker to assess "recapture" rates. However, both the state scientific collection permit (SCP) and the federal special purpose utility permit (SPUT) enabling surveyors to handle carcasses were still being processed during this sampling period so no mark-recapture data was collected. Scavenger removal trials and searcher efficiency trials were also not performed due to the lack of handling permits. Therefore, all estimates presented in this report represent mortality estimates that are uncorrected for observer bias and scavenger removal rates. Future reports will address these biases, once permits are approved by the FWS and CDFW.

2.2 Analysis

Two primary analyses were proposed for mortality estimation. The first analysis used Program DISTANCE to determine the most effective transect width to search for carcasses. Distance models examined a variety of detection functions and used Aikake's Information Criterion (AIC)[1] for model selection. Models were run using both no truncation as well as 5% upper truncation to remove outliers. Specific model components are discussed in **Section 3.2**.

The second analysis would use Program MARK to estimate total number of mortalities controlling for detection rate, scavenging rate, and proximity to Project components. However, as described above, handling permits have not been approved by either the FWS or CDFW. Thus, mark-recapture protocols could not be implemented. Future reports will contain a mark-recapture analysis, pending approval of handling permits. Alternative analysis packages may be considered (as opposed to Program MARK); see **Section 4.4** for additional discussion of potential statistical analyses.

Project mortality estimates rely on measuring a daily mortality rate that can be used as the basis for all mortality estimates. To calculate the corrected project mortality estimate, we did not count all mortalities observed during day 1 of the 7-day search period under the assumption that the those mortalities represent "bleed through" from the period prior to 24 hours preceding the first search. To accurately generate a rate, all mortalities used for this analysis need to have occurred within the 24 hours preceding discovery. Mortalities observed during the subsequent 6 days were then up-corrected to adjust for time not searched

---

[1] AIC measures the relative quality of a given model by assessing both the model's complexity as well as the model goodness-of-fit to the observed data. Lower AIC values indicate higher quality models. Typically AIC values are compared among several possible models to select the "best" model or models.

(since the search period captured 6 out of 28, 30 or 31 days each month), producing a time-corrected mortality estimate for each month.

Because taxonomic analyses do not use a rate, but are instead only concerned with the overall breakdown in mortalities, these analyses used all recorded mortality data, including those mortalities observed during day 1 of the 7-day search period. The use of these data from day one assumes that there is not persistence bias for different taxa of birds. Once scavenger removal trials are approved, this assumption can be tested and analyses will be adjusted if necessary.

3 Results

3.1 Overall Mortalities Observed

The three months of surveys were conducted from November 19-25, 2014; December 16-22, 2014; and, January 20-26, 2015. A total of 26 avian mortalities were recorded. Nineteen (19) of these observed mortalities were recorded as "feather spots". **Table 1** provides a breakdown of mortalities by sampling period.

Table 1 – Observed Mortalities by Sampling Period

Mortality Type	November (11/19/14 – 11/25/14)	December (12/16/14 – 12/22/14)	January (1/20/15 – 1/26/15)	Nov.-Jan. 2014/2015 TOTAL
Feather Spot Mortalities	3	6	10	19
Non-Feather Spot Mortalities	5	0	3	8
Total Mortalities	*8*	*6*	*13*	*27*

The inclusion of feather spots as observed mortalities is based on standard mortality monitoring protocols, which were largely developed for the wind energy industry. At wind energy facilities, the speed of the spinning blades can result in mortalities that leave very little detectible carcass behind, including only feather spots. Inclusion of feather spots as recorded mortalities at these facilities was intended to conservatively include mortalities caused by blade strikes that might otherwise go unrecorded. Potential bias resulting from the inclusion of feather spots in mortality data can arise from feather spots meeting the definition of a mortality but not actually resulting from an avian mortality. This bias can lead to overestimates of mortality rates. This bias is problematic in situations where feathers are commonly deposited in non-mortality related events but get included as incidents of avian morality (e.g. in and around common roost or perch sites, near active nests, etc.). Feather spots may also be caused by predation or attempted-predation events within a survey area. Observers used discretion when encountering feather spots to help mitigate this bias. Feather spots that strongly indicated a deposition of feathers that was unrelated to an avian mortality or injury were excluded from the database; in instances where observers were uncertain, the feathers spots were recorded as mortalities in order to be conservative. All of the following analyses present results that both include and exclude feather spots to present the full range of possible mortalities.

3.2 Effective Transect Width

DISTANCE analyses were performed using the data pooled across the three-month sampling period and **Tables 2-5** present the results of the DISTANCE analysis. It is important to note several models had errors likely arising from small sample sizes. These errors included model parameters being constrained to obtain monotonicity[2], parameters at lower bounds[3] and highly correlated parameters. Models were run that included and excluded feather spot as well as models that truncated the data and models that employed no truncation.

---

[2] DISTANCE analyses rely on the modeling of a detection function. This detection function models the change in probability of detecting a carcass as the distance from the transect increases. This type of modelling relies on the assumption that the detection function is monotonic. Monotonic means that the probability of detection *only* changes in one direction (decreases) with increasing distance from the transect. If the detection probability goes up and down as distance from the transect increases, then the results violate this assumption of monotonicity. Program DISTANCE automatically constrains certain model parameters to obtain monotonicity but the resulting model may have a poor fit to the observed data.

[3] Similar error to footnote 2.

The a priori[4] estimate of effective transect width was approximately 8.4 meters (this represents the width of two panel rows measured from the pier of the panel immediately east of the designated transects to the pier of the second panel to the west of the transect). Generally, the most likely models were consistent with or exceeded that assumption. Sample sizes were small for all models run this quarter and model results should be used with some caution. Many of the errors encountered are likely the result of small sample sizes.

3.3 Searcher Bias

As described above, permits allowing observers to handle bird carcasses had not been issued at the time of these surveys. As such, no searcher bias estimates were generated and overall mortality estimates were not adjusted to reflect searcher bias.

3.4 Scavenger Removal Bias

As described above, permits allowing observers to handle bird carcasses had not been issued at the time of these surveys. As such, no scavenger removal trials were completed and overall mortality estimates were not adjusted to reflect scavenger removal bias.

3.5 Corrected Project Mortality Estimate

Results from surveys conducted each month were used to generate discrete mortality estimates for each month surveyed. Monthly and overall project mortality estimates only used data from search days 2-7 (see **Section 2.2**). Monthly mortality estimates were used in order to detect seasonal variations in mortality rates. Also, data are presented to reflect estimates with and without feather spots, as discussed earlier. For the remainder of this section, mortality values are presented as “number of mortalities excluding feather spots”/“number of mortalities inclusive of feather spots”.

While results of the DISTANCE analyses were less than conclusive, they were at least consistent with the a priori assumption of a minimum 8.4-meter effective transect width. Transect layout, in consideration of this assumed effective transect width, was designed to sample 10% of the overall PV array area. The time-corrected mortality estimates for each month were again up-corrected to account for the area not surveyed. Since no searcher efficiency or scavenger removal bias corrections were performed, this time- and area-corrected mortality estimate represents the overall monthly project mortality estimate. Mortality estimates were rounded to the nearest whole number. **Table 6** summarizes the corrected mortality estimates by month.

3.5.1 November Mortalities

A total of 4/6 mortalities were detected during days 2-7 of the November surveys. Correcting for time (the 6 day survey period represents approximately 20% of the total days in November) and area surveyed, the overall monthly project mortality estimate for November was 200/300.

3.5.2 December Mortalities

A total of 0/4 mortalities were detected during days 2-7 of the December surveys. Correcting for time (the 6 day survey period represents approximately 19% of the total days in December) and area surveyed, the overall monthly project mortality estimate for December was 0/207.

3.5.3 January Mortalities

A total of 2/8 mortalities were detected during days 2-7 of the January surveys. Correcting for time (the 6 day survey period represents approximately 19% of the total days in January) and area surveyed, the overall monthly project mortality estimate for January was 103/413.

3.5.4 November 2014 –January 2015 Corrected Mortality Estimates

After applying time and area corrections to the mortality counts for each month the overall project mortality estimate for the period November of 2014 to January of 2015 is 303/920.

Table 6 – Corrected Mortalities by Month

	November		December		January		Nov-Jan. Totals	
	Exc. Feather Spots	**Inc. Feather Spots**	**Exc. Feather Spots**	**Inc. Feather Spots**	**Exc. Feather Spots**	**Inc. Feather Spots**	**Exc. Feather Spots**	**Inc. Feather Spots**
Raw Mortality Count (days 2-7)	4	6	0	4	2	7	5	17
Corrected Mortality Estimate	200	300	0	207	103	413	303	920

3.6 Taxonomic Composition of Observed Mortalities

The following analyses use all observed mortalities including those detected on search day 1 since the taxonomic composition is not a rate-dependent analysis (see **Section 2.2**).

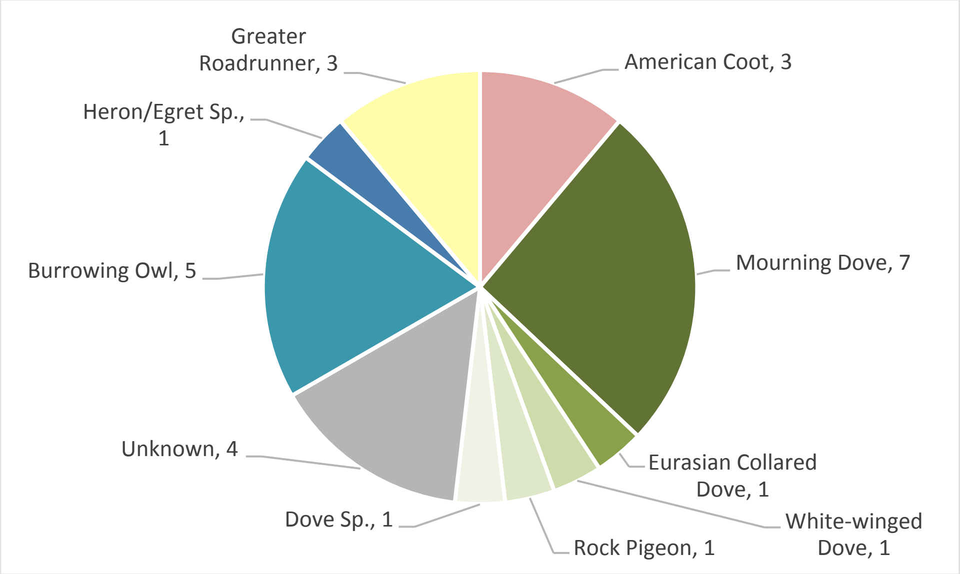
Table 7 – Raw Mortalities by Month (includes data from all search days)

	November		December		January		Nov-Jan. Totals	
	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots
Raw Mortality Count (days 1-7)	5	8	0	6	3	12	8	27

3.6.1 Mortalities Including Feather Spots

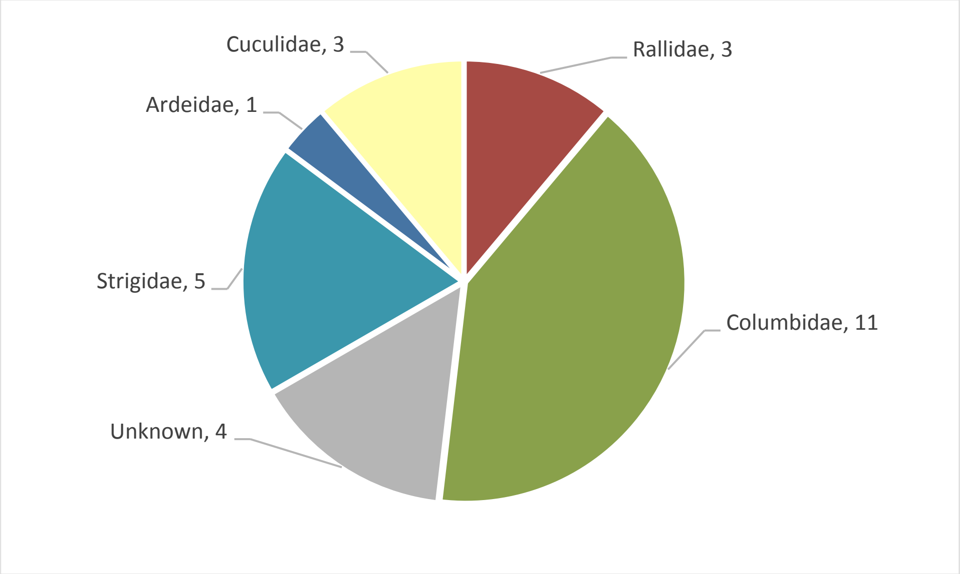
A total of 27 mortalities were observed when feather spots were included in the data set. Four (4) of these mortalities (15%) could not be identified to species. Of the 23 carcasses that could be identified to species, the most commonly observed species were Mourning Dove (*Zenaida macroura*; 7 mortalities; 30% of mortalities identified to species) and Burrowing Owl (*Athene cunicularia*; 5 mortalities; 22% of mortalities identified to species). **Figure 2** presents the breakdown of observed mortalities by species.

Figure 2 – Mortalities by Species (includes feather spots)



Twenty-three (23) of the 27 observed mortalities could be identified to the family level. Of these 23 mortalities, the families Columbidae (11 mortalities; 48% of mortalities identified to family level) and Strigidae (5 mortalities; 22% of mortalities identified to family level) were the most commonly observed mortalities. **Figure 3** presents the breakdown of observed mortalities by family.

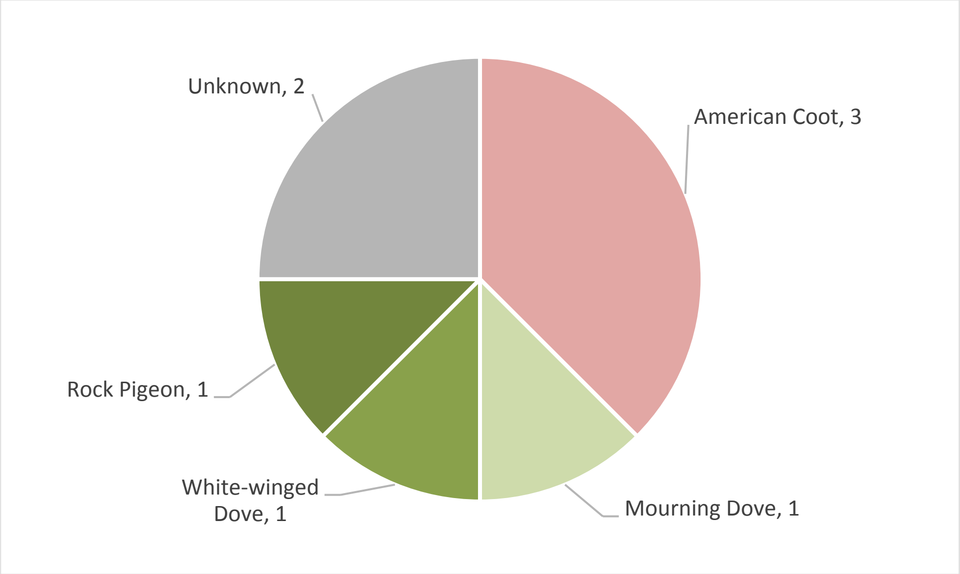
Figure 3 – Mortalities by Family (includes feather spots)



3.6.2 Mortalities Excluding Feather Spots

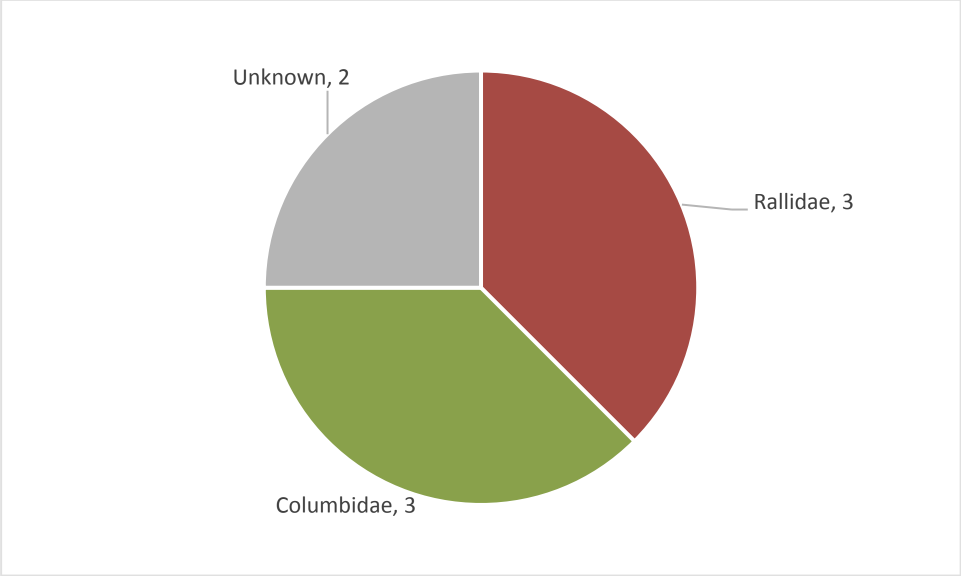
A total of eight (8) mortalities were observed when feather spots were excluded from the data set. Six (6) of these mortalities (75%) could be identified to species. Of the 6 carcasses that could be identified to species, American Coot (*Fulica Americana*; 3 mortalities; 50% of the mortalities identified to species) was the most commonly observed. **Figure 4** presents the breakdown of observed mortalities by species.

Figure 4 - Mortalities by Species (excludes feather spots)



Six (6) of the 8 observed mortalities could be identified to the family level. Of these mortalities, the families Columbidae (3 mortalities; 50% of mortalities identified to family level) and Rallidae (3 mortalities; 50% of mortalities identified to family level) were the most commonly observed. **Figure 5** presents the breakdown of observed mortalities by family.

Figure 5 – Mortalities by Family (excludes feather spots)



4 Discussion

4.1 Mortality Estimates

Searcher efficiency and scavenger removal trials can only result in up-correcting results (since searchers cannot detect >100% of carcasses and scavengers are unlikely to deposit carcasses within a survey area). Because searcher efficiency and scavenger removal trials were not performed during the second quarter surveys, the degree of underestimation is unknown. As soon as the Centinela Solar Energy Project receives a SPUT permit from FWS and a SCP from CDFW, searcher efficiency and scavenger removal trials will begin.

4.2 Seasonal Variations

There was some variation in estimated mortality rates from month to month, especially within the dataset excluding feather-spot mortalities. The December estimated mortality rate was 0/207, whereas November and January estimated mortality rates were appreciably higher (200/300 and 103/413, respectively). It should be noted that the sample size of observed mortalities was fairly low this quarter (especially relative to the magnitude of the correction factors), making these types of analyses difficult to achieve with high confidence levels.

4.3 Recommended Methodological Changes

The following changes are recommended to improve survey efficiency and accuracy as well as to improve data collection and analysis.

1. Searcher Efficiency and Scavenger Removal Bias – The results presented in this report are uncorrected for searcher efficiency and scavenger removal. Searcher efficiency at this site is likely very high (near 100%) given the level ground and almost entirely unvegetated environment. As such, the searcher efficiency bias is unlikely to have resulted in a significant underestimate of mortality. However, scavenger removal rates are unknown and could be a source of bias. Numerous potential avian and mammalian scavengers are known to occur in and around the project site. Until scavenger removal trials are performed, the magnitude of this source of bias is unknown. As soon as state and federal permits are approved, these trials will be initiated.
2. Alternative Statistical Analysis Packages – Since the publication of the project BBCS (Heritage 2012), a potentially more robust mortality estimation program has been released for use with the statistical analysis software Program R, called *facilityCMR*. This program offers several potential advantages over the Warren-Hicks Estimator including analyzing covariance between searcher efficiency and scavenger removal rates and allowing for analysis of carcass condition. We propose using the *facilityCMR* software in future analyses, as soon as searcher efficiency and scavenger removal trials are permitted. This would be used in lieu of the Warren-Hicks Estimator and Program MARK and better reflects current FWS guidance on mortality studies at solar facilities.

Post-construction Avian Mortality Monitoring Report
Campo Verde Solar Project

Third Quarter 2014 (July, August, September)

and

Year 1 Annual Report (October 2013 – September 2014)

Prepared By:

Heritage Environmental Consultants, LLC

December 2014

Table of Contents

1 Introduction

The Campo Verde Solar Project is a solar photovoltaic (PV) energy generating facility (Solar Energy Facility) and an associated electrical transmission line (Gen-Tie Line) in southern Imperial County, California. The solar project is located on private lands and the gen-tie line is located on private and federal lands managed by the Bureau of Land Management (BLM). These are referred to collectively as the "project."

A Bird and Bat Conservation Strategy (BBCS) was prepared that addresses activities potentially occurring during construction and operation of the project (Heritage 2013). The BBCS was reviewed and approved by the U.S. Fish and Wildlife Service (FWS), California Department of Fish and Wildlife (CDFW), and BLM. The purpose of the Campo Verde BBCS was to develop and implement a program to identify and avoid risks to avian and bat species that could result from construction and operation of the project. The goal of this BBCS was to implement a series of best practices, in order to construct and operate the project to avoid or reduce risk to birds, bats and their habitats.

The post-construction avian mortality monitoring program was set up to comply with the methodology prescribed in the BBCS (Heritage 2013). The methodology is described in Section 6.1 of the BBCS and was approved by the FWS and CDFW. Quarterly reports documenting results of the monitoring program are required for the first year of program, and annually thereafter. Monitoring began in October 2013 just after completion of construction. This report is the fourth of four quarterly reports for the first survey year and also provides a summary of the entire first year's results. Periodic reporting will shift to annual (rather than quarterly) after this report.

1.1 Project Description

The general location of the project is approximately 7 miles southwest of the city of El Centro, Imperial County, California (**Figure 1**). The project is south of I-8, west of Drew Road, and northeast and south of the Westside Main Canal. The Project consists of two component parts: (i) the Solar Energy Facility and (ii) an approximately 0.9-mile, 230-kilovolt (kV) aboveground, electrical gen-tie line and associated facilities that electrically connects the Solar Energy Facility on private land with the Imperial Valley Substation (IV Substation) located on federal land managed by the BLM.

The Solar Energy Facility is approximately 1,443 acres in size and uses First Solar PV modules that are generally non-reflective and convert sunlight into direct current (DC) electricity. The DC output of multiple rows of PV modules is collected through one or more combiner boxes and directed to an inverter that converts the DC electricity to alternating current (AC) electricity. From the inverter, the generated energy flows to a transformer where it is stepped up to distribution level voltage (approximately 34.5 kV). Multiple transformers are connected in parallel via 34.5 kV lines to the project substation, where the power is stepped up to 230 kV. This substation is located at the southern end of the Solar Energy Facility near Liebert Road. The Gen-Tie Line connects the project substation to the Imperial Valley Substation approximately 0.9 miles to the south.

The Gen-Tie Line uses double-circuit tubular steel monopole structures. Tower structure heights range from 100 to 135 feet. One side of the double-circuit structures currently supports three two- bundle conductors and one shield wire. Typical overall structure widths are approximately 20 feet.

Project Facilities

2 Methods

Monitoring of the project was performed in order to document and report avian mortalities and identify areas of concern by tracking both the specific locations where mortalities occur as well as the extent of such mortalities. The monitoring program for the project is based on the FWS guidance entitled "Monitoring Migratory Bird Take at Solar Power Facilities: An Experimental Approach" (FWS 2012) with modifications, and was approved by FWS.

2.1 Transect Sampling

Sampling transects were established for both the gen-tie line and solar field. For each kilometer of Gen-Tie Line, 300-meter transects were randomly established along the Gen-Tie Line allowing for approximately 30-percent of the Gen-Tie Line to be sampled. Transects were positioned along the centerline of the Gen-Tie Line. For the Campo Verde Solar Energy Facility, transects were also positioned to result in approximately 30-percent coverage of the site with no less than eight transects placed within the solar field itself. Transect selection was systematic randomized. The entire perimeter of the panel arrays was also surveyed during each survey period in addition to the interior transects.

Transects were surveyed for 7 consecutive days each month and each transect was surveyed once daily. Because of the large number of transects, sampling periods were 14-days; the first half of transects were walked for 7-day period and the second half for another 7-day period. One qualified observer walked along the pre-determined transects searching for bird/bat carcasses. When a carcass was observed, a GPS location was recorded at the carcass, the species was identified, the perpendicular distance from the transect to the carcass was measured, and information regarding carcass condition per FWS (2012) was recorded using paper datasheets. Once data were collected at a carcass, the observer returned to the pre-determined transect and continued with the survey.

The original protocol stated that each carcass would be marked uniquely and inconspicuously with tape and permanent marker to assess "recapture" rates. The federal special purpose utility permit (SPUT) was received in September of 2014 while the state scientific collection permit (SCP) enabling surveyors to handle carcasses was issued in November of 2014. The mark-recapture data, scavenger removal trials, and searcher efficiency trials will commence during the Q1 monitoring period. Therefore, all estimates presented in this report represent mortality estimates that are uncorrected for observer bias and scavenger removal rates. Future reports will address these biases.

2.2 Analysis

Two primary analyses were proposed for mortality estimation. The first analysis used Program DISTANCE to determine the most effective transect width to search for carcasses. Distance models examined a variety of detection functions and used Aikake's Information Criterion (AIC)[1] for model selection. DISTANCE modeling was run using both a 5% upper truncation to remove outliers and without any truncation. Specific model components are discussed in **Section 3.2**.

The second analysis would use Program MARK to estimate total number of mortalities controlling for detection rate, scavenging rate, and proximity to Project components. The mark-recapture protocols were not implemented during this mortality estimation, but will be implemented during future analyses and presented in future reports. Alternative analysis packages may be considered (as opposed to Program MARK); see **Section 4.3** for additional discussion of potential statistical analyses.

Project mortality estimates rely on measuring a daily mortality rate that can be used as the basis for all mortality estimates. To calculate the corrected project mortality estimate, we did not count all mortalities

---

[1] AIC measures the relative quality of a given model by assessing both the model's complexity as well as the model goodness-of-fit to the observed data. Lower AIC values indicate higher quality models. Typically AIC values are compared among several possible models to select the "best" model or models.

observed during day 1 of the 7-day search period under the assumption that the those mortalities represent "bleed through" from the period prior to 24 hours preceding the first search. To accurately generate a rate, all mortalities used for this analysis need to have occurred within the 24 hours preceding discovery. Mortalities observed during the subsequent 6 days were then up-corrected to adjust for time not searched (since the search period captured 6 out of 28, 30 or 31 days each month), producing a time-corrected mortality estimate for each month.

Because taxonomic analyses do not use a rate, but are instead only concerned with the overall breakdown in mortalities, these analyses used all recorded mortality data, including those mortalities observed during day 1 of the 7-day search period. The use of these data from day one assumes that there is not persistence bias for different taxa of birds. Once scavenger removal trials are approved, this assumption can be tested and analyses will be adjusted if necessary.

3 Results

This report presents the results of the Q3 2014 surveys separately from the summary of Year 1 results. **Section 3.1** presents the results from Q3 only since these results have not yet been documented in a report. **Section 3.2** summarizes the entire first year of monitoring and includes data from October 2013 through September 2014.

3.1 Q3 2014 Results

3.1.1 Overall Mortalities Observed

Third quarter surveys for 2014 were conducted from July 12-25, 2014; August 9-22, 2014; and, September 6-19, 2014. A total of 30 avian mortalities were recorded. Four (4) of these observed mortalities were recorded as "feather spots". **Table 1** provides a breakdown of mortalities by sampling period.

Table 1 – Observed Mortalities by Sampling Period

Mortality Type	July (7/12/14 – 7/25/14)	August (8/9/14 – 8/22/14)	September (9/6/14 – 9/19/14)	Q3 2014 TOTAL
Non- Feather Spot Mortalities	7	9	10	26
Feather Spot Mortalities	0	3	1	4
Total Mortalities	*7*	*12*	*11*	*30*

The inclusion of feather spots as observed mortalities is based on standard mortality monitoring protocols, which were largely developed for the wind energy industry. At wind energy facilities, the speed of the spinning blades can result in mortalities that leave very little detectible carcass behind, including only feather spots. Inclusion of feather spots as recorded mortalities at these facilities was intended to conservatively include mortalities caused by blade strikes that might otherwise go unrecorded. Potential bias resulting from the inclusion of feather spots in mortality data can arise from feather spots meeting the definition of a mortality but not actually resulting from an avian mortality. This bias can lead to overestimates of mortality rates. This bias is problematic in situations where feathers are commonly deposited in non-mortality related events but get included as incidents of avian morality (e.g. in and around common roost or perch sites, near active nests, etc.). Feather spots may also be caused by predation or attempted-predation events within a survey area. Based on the large proportion of feather spots observed during the Q4 2013 and Q1 2014 surveys (63% and 41%, respectively), observers used greater discretion when encountering feather spots to help mitigate this bias. Feather spots that strongly indicated a deposition of feathers that was unrelated to an avian mortality or injury were excluded from the database; in instances where observers were uncertain, the feathers spots were recorded as mortalities in order to be conservative. All of the following analyses present results that both include and exclude feather spots to present the full range of possible mortalities.

A single Mexican free-tailed bat (*Tadarida brasiliensis*) carcass was found on August 9 underneath a solar panel. Due to differences in detection probabilities between mammals and birds, this mortality is not included in summary statistics included later in this report.

3.1.2 Effective Transect Width

DISTANCE analyses were performed using the data pooled across the three-month sampling period and **Table 2** presents the results of the DISTANCE analysis run using no truncation. It is important to note that none of the models fit the data well. In addition to parameters being constrained to obtain monotonicity[2], other modelling issues, including high levels of correlation and invalid variance estimates were present in several models[3]. The uniform – polynomial model was not able to run as a result of these problems. A second DISTANCE analysis was completed using 5% upper truncation (**Table 3**). Overall model performance using this truncation was slightly better but still did not result in reliable models. Model parameters were highly correlated in the half-normal – hermite model and parameters were at lower bounds in the hazard – cosine model[4]. Overall sample sizes were very small during Q3 of 2014 (n=17), which is likely the primary factor limiting the reliability of the DISTANCE analysis.

Table 2 – Distance Analysis Results with no truncation– includes feather spots

---

[2] DISTANCE analyses rely on the modeling of a detection function. This detection function models the change in probability of detecting a carcass as the distance from the transect increases. This type of modelling relies on the assumption that the detection function is monotonic. Monotonic means that the probability of detection *only* changes in one direction (decreases) with increasing distance from the transect. If the detection probability goes up and down as distance from the transect increases, then the results violate this assumption of monotonicity. Program DISTANCE automatically constrains certain model parameters to obtain monotonicity but the resulting model may have a poor fit to the observed data.

[3] These are other constraints placed on the model in order to ensure that the model definitions meet basic assumptions. These errors indicate that data input into the models does not reliable meet the assumptions of DISTANCE analysis and interpretation of these results should use caution.

[4] This issue is the similar to parameter constraints to obtain monotonicity. In this case, the parameters are not at the point of requiring constraint to maintain assumptions but are at the limit of what can be tolerated while still maintaining monotonicity.

Hazard – Cosine**	2	133.45	1.99	0.00	0.00-0.00	7.09

*Some parameters are very highly correlated
**Some parameters are at lower bound.

The a priori[5] estimate of effective transect width was approximately 7.5 meters (this represents the width of two panel rows measured from the bottom of the panel immediately north of the designated transects to the bottom of the second panel to the south of the transect). Generally, the most likely models were consistent with or exceeded that assumption. Sample sizes were small for all models run this quarter and model results should be used with a high degree of caution (e.g. note that modeled density was rounded to 0.00 for all model definitions as a results of low sample sizes and unreliable model results).

3.1.3 Searcher Bias

No searcher bias estimates were generated and overall mortality estimates were not adjusted to reflect searcher bias within this report.

3.1.4 Scavenger Removal Bias

No scavenger removal trials were completed and overall mortality estimates were not adjusted to reflect scavenger removal bias within this report.

3.1.5 Corrected Project Mortality Estimate

Results from surveys conducted each month were used to generate discrete mortality estimates for each month surveyed. Monthly and overall project mortality estimates only used data from search days 2-7 (see **Section 2.2**). Monthly mortality estimates were used in order to detect seasonal variations in mortality rates. Also, data are presented to reflect estimates with and without feather spots, as discussed earlier. For the remainder of this section, mortality values are presented as "number of mortalities excluding feather spots"/"number of mortalities inclusive of feather spots".

While results of the DISTANCE analyses were less than conclusive, they were at least consistent with the a priori assumption of a minimum 7.5-meter effective transect width. Past quarterly DISTANCE analyses for this study have also supported the validity of the 7.5-meter transect. Transect layout, in consideration of this assumed effective transect width, was designed to sample 30% of the overall PV array area. The time-corrected mortality estimates for each month were again up-corrected to account for the area not surveyed. Since no searcher efficiency or scavenger removal bias corrections were performed, this time- and area-corrected mortality estimate represents the overall monthly project mortality estimate. Mortality estimates were rounded to the nearest whole number. **Table 4** summarizes the corrected mortality estimates by month.

3.1.5.1 July Mortalities

A total of 3/3 mortalities were detected during days 2-7 of the July surveys. Correcting for time (the 6 day survey period represents approximately 19% of the total days in July) and area surveyed, the overall monthly project mortality estimate for July was 52/52 mortalities.

3.1.5.2 August Mortalities

A total of 7/8 mortalities were detected during days 2-7 of the August surveys. Correcting for time (the 6 day survey period represents approximately 19% of the total days in August) and area surveyed, the overall monthly project mortality estimate for August was 36/41 mortalities.

---

[5] "A priori" hypotheses are those hypothesis developed based on a theoretical and logical understanding of the system in question and not based on empirical results. That is, a priori hypothesis are those generated before any results have been collected.

3.1.5.3 September Mortalities

A total of 5/6 mortalities were detected during days 2-7 of the September surveys. Correcting for time (the 6 day survey period represents approximately 20% of the total days in September) and area surveyed, the overall monthly project mortality estimate for September was 83/100.

3.1.5.4 Third Quarter 2014 Corrected Mortality Estimates

After applying time and area corrections to the mortality counts for each month the overall project mortality estimate for the third quarter of 2014 is 256/289 birds.

Table 4 – Corrected Mortalities by Month

	July		August		September		Q3 Totals	
	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots
Raw Mortality Count (days 2-7)	3	3	7	8	5	6	15	17
Corrected Mortality Estimate	52	52	121	138	83	100	256	289

3.1.6 Taxonomic Composition of Observed Mortalities

The following analyses use all observed mortalities including those detected on search day 1 since the taxonomic composition is not a rate-dependent analysis (see **Section 2.2**).

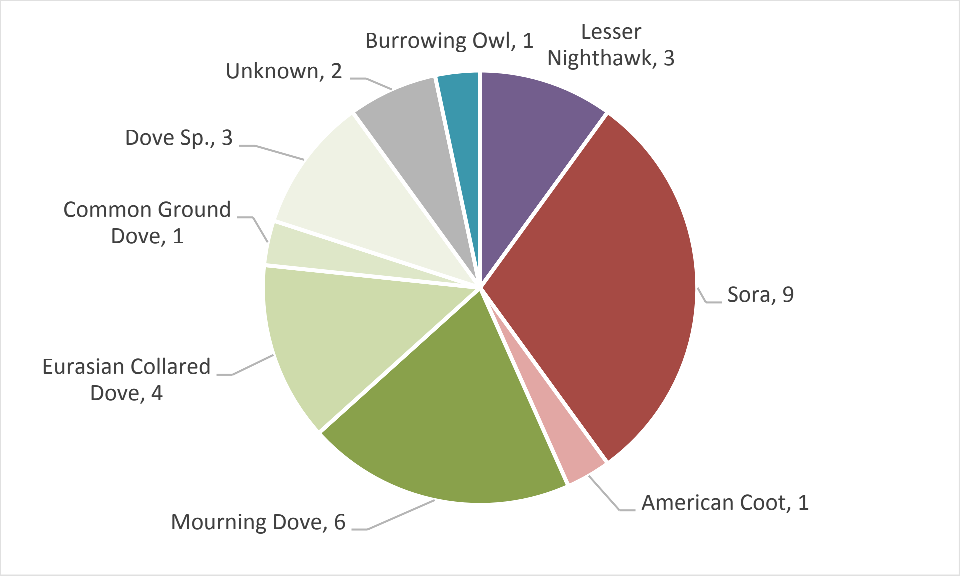
Table 5 – Raw Mortalities by Month (includes data from all search days)

	July		August		September		Q3 Totals	
	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots	Exc. Feather Spots	Inc. Feather Spots
Raw Mortality Count (days 1-7)	7	7	9	12	10	11	26	30

3.1.6.1 Mortalities Including Feather Spots

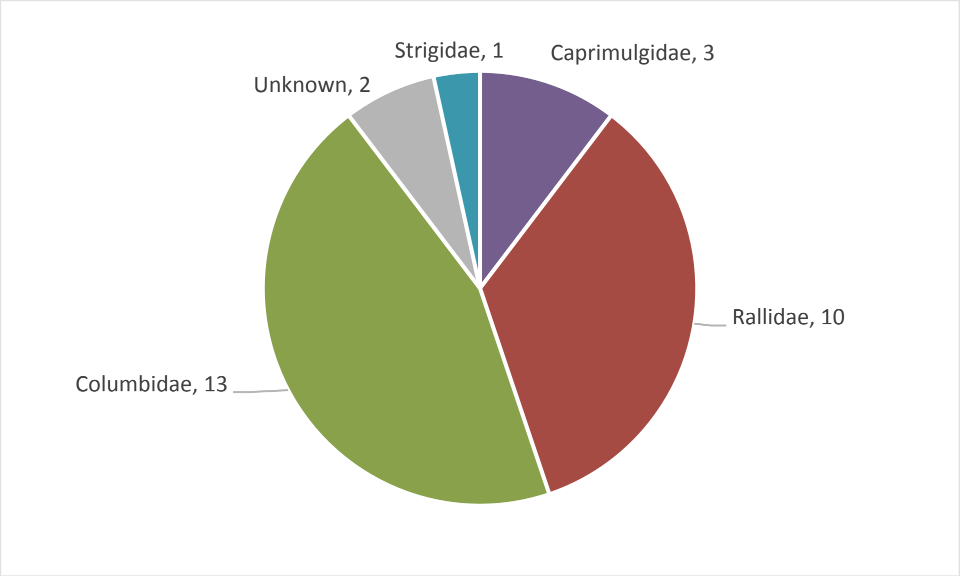
A total of 30 mortalities were observed when feather spots were included in the data set. Five (5) of these mortalities (17%) could not be identified to species. Of the 25 carcasses that could be identified to species, the most commonly observed species were Sora (*Porzana Carolina*; 9 mortalities; 36% of mortalities identified to species level), Mourning Dove (*Zenaida macroura*; 6 mortalities; 24% of mortalities identified to species level), and Eurasian Collard Dove (*Streptopelia decaocto*; 4 mortalities; 16% of mortalities identified to species level). **Figure 2** presents the breakdown of observed mortalities by species.

Figure 2 – Mortalities by Species (includes feather spots)



Twenty-eight (28) of the 30 observed mortalities could be identified to the family level. Of these 28 mortalities, the families Columbidae (14 mortalities; 50% of mortalities identified to family level) and Rallidae (10 mortalities; 36% of mortalities identified to family level) were the most commonly observed mortalities. **Figure 3** presents the breakdown of observed mortalities by family.

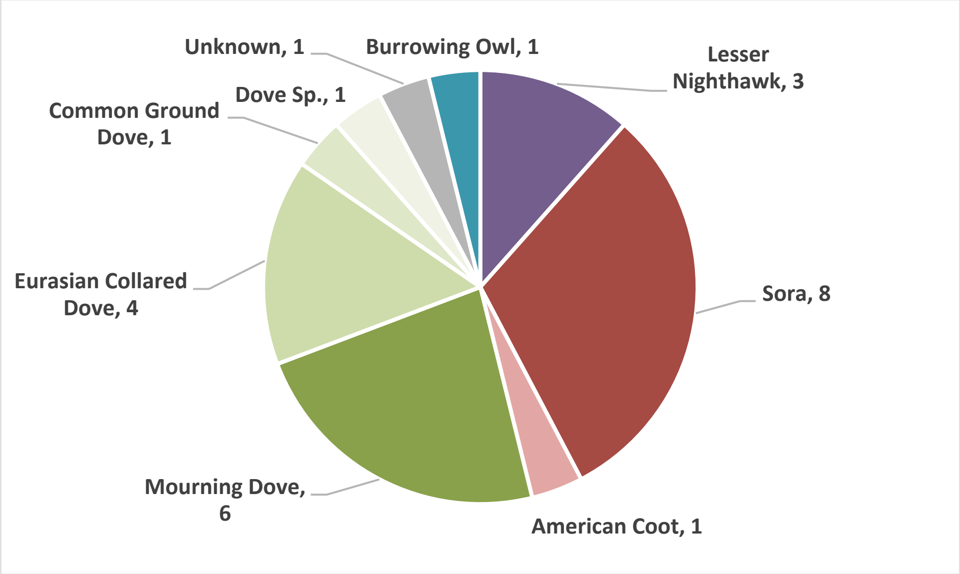
Figure 3 – Mortalities by Family (includes feather spots)



3.1.6.2 Mortalities Excluding Feather Spots

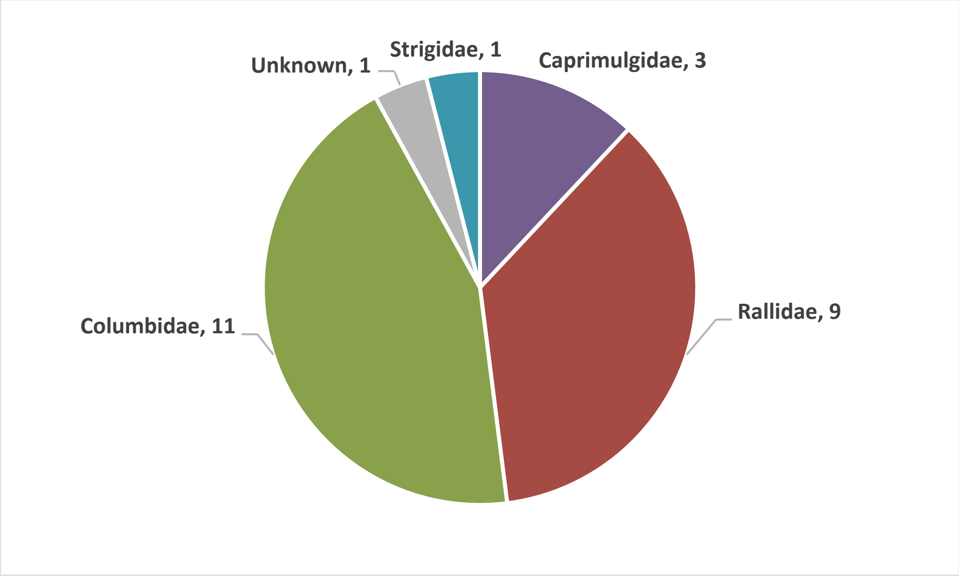
A total of 26 mortalities were observed when feather spots were excluded from the data set. Twenty-four (24) of these mortalities (92%) could be identified to species. Of these 24 carcasses, the most commonly observed species were Sora (8 mortalities; 33% of mortalities identified to species), Mourning Dove (6 mortalities; 25% of mortalities identified to species), and Eurasian Collared Dove (4 mortalities; 17% of mortalities identified to species). **Figure 4** presents the breakdown of observed mortalities by species.

Figure 4 - Mortalities by Species (excludes feather spots)



Twenty-five (25) of the 26 observed mortalities (96%) could be identified to the family level. Of these 25 mortalities, the families Columbidae (12 mortalities; 48% of mortalities identified to species level) and Rallidae (9 mortalities; 36% of mortalities identified to family level) were the most commonly observed. **Figure 5** presents the breakdown of observed mortalities by family.

Figure 5 – Mortalities by Family (excludes feather spots)



3.2 Annual Results Summary (October 2013 – September 2014)

3.2.1 Overall Mortalities Observed

A total of 93 avian mortalities were recorded during the first year of surveys. Thirty-nine (39) of these observed mortalities were recorded as “feather spots”. **Table 6** provides a breakdown of mortalities by sampling period. As discussed in **Section 3.1.1**, all of the following analyses present results that both include and exclude feather spots to present the full range of possible mortalities.

Table 6 – Observed Mortalities by Sampling Period

Mort. Type	Q4 2013			Q1 2014			Q2 2014			Q3 2014			*Total*
	Oct. 2013	Nov. 2013	Dec. 2013	Jan. 2014	Feb. 2014	Mar. 2014	Apr. 2014	May 2014	Jun. 2014	Jul. 2014	Aug. 2014	Sep. 2014	
Feather Spot Mort.	6	15	2	8	1	0	2	0	1	0	3	1	*39*

3.2.1 Effective Transect Width

DISTANCE analyses were performed using the data pooled across the twelve-month sampling period. Analyses were run that both included and excluded feather spots as were analyses that both truncated the upper 5% of the data and left the data untruncated. **Tables 7-10** presents the results of the DISTANCE analyses run. It is important to note that none of the models fit the data well. Multiple errors occurred due to parameters being constrained to obtain monotonicity and some parameters exhibiting high correlation. Overall sample sizes were very small relative to the area sampled during the first year of surveys, which is likely the primary factor limiting the reliability of the DISTANCE analysis.

*Some parameters were constrained to obtain monotonicity.
**Some parameters are very highly correlated

The a priori estimate of effective transect width was approximately 7.5 meters (this represents the width of two panel rows measured from the bottom of the panel immediately north of the designated transects to the bottom of the second panel to the south of the transect). Generally, the most likely models were consistent with or exceeded that assumption. Sample sizes were small for all models run this quarter and model results should be used with a high degree of caution (e.g. note that modeled density was rounded to 0.00 or 0.001 for all model definitions as a results of low sample sizes and unreliable model results).

3.2.2 Searcher Bias

No searcher bias estimates were generated and overall mortality estimates were not adjusted to reflect searcher bias within this annual report.

3.2.3 Scavenger Removal Bias

No scavenger removal trials were completed and overall mortality estimates were not adjusted to reflect scavenger removal bias during the surveys completed during Q4 of 2013 through Q3 of 2014.

3.2.1 Corrected Project Mortality Estimate

Results from surveys conducted each month were used to generate discrete mortality estimates for each month surveyed. Monthly and overall project mortality estimates only used data from search days 2-7 (see **Section 2.2**). Monthly mortality estimates were used in order to detect seasonal variations in mortality rates. Also, data are presented to reflect estimates with and without feather spots, as discussed earlier. For the remainder of this section, mortality values are presented as “number of mortalities excluding feather spots”/“number of mortalities inclusive of feather spots”.

While results of the DISTANCE analyses were less than conclusive, they were at least consistent with the a priori assumption of a minimum 7.5-meter effective transect width. Transect layout, in consideration of this assumed effective transect width, was designed to sample 30% of the overall PV array area. The time-corrected mortality estimates for each month were again up-corrected to account for the area not surveyed. Since no searcher efficiency or scavenger removal bias corrections were performed, this time- and area-corrected mortality estimate represents the overall monthly project mortality estimate. Mortality estimates were rounded to the nearest whole number. **Table 11** summarizes the corrected mortality estimates by month. **Figure 6** shows the trend of corrected mortality estimates over the course of the year’s surveys.

Table 11 – Corrected project mortality by month

AVIAN MORTALITY AT A SOLAR ENERGY POWER PLANT

By Michael D. McCrary, Robert L. McKernan,
Ralph W. Schreiber, William D. Wagner,
and Terry C. Sciarrotta

In 1979, the United States Department of Energy, in conjunction with the Southern California Edison Company (SCE) and the Los Angeles Department of Water and Power, initiated the construction of Solar One, the world's largest solar energy power plant (Fig. 1). Until the construction of Solar One, the use of the sun's energy to produce electrical power had not been attempted on this scale, and the environmental hazards of operation of a solar power plant were unknown. In this paper we report on bird mortality at Solar One.

STUDY AREA AND METHODS

Solar One is a 10 megawatt, central receiver solar power plant consisting of a 32-ha field of 1818, 6.9 × 6.9 m mirrors (heliostats) which concentrate sunlight on a centrally located, tower-mounted boiler, 86 m in height (Fig. 1). The reflective surface area of each heliostat is approximately 40 m^2, and the total for all heliostats is approximately 72,500 m^2. When not directed at the tower during morning startup, testing, and maintenance, some or all of the heliostats are focused on standby points, four small areas (approximate diameter = 5 m) of sky around the tower at a height of 80 m. Temperatures within the standby points vary with the number of heliostats focused on them and the reflectivity of an object placed within them, but the temperature can be high enough to burn feathers and small insects.

Solar One is located in the Mojave Desert, 4 km east of Daggett, San Bernardino County, California (34°52′N, 116°51′W). The dominant desert plant community in this area is creosote bush (*Larrea divaricata*) scrub, although abandoned and active agricultural fields (alfalfa) and extensive (53 ha) evaporation ponds (Fig. 1) are adjacent to Solar One.

We visited Solar One approximately once per week (2–3 days per visit) on 6 occasions from 3 May through 8 June 1982 and on 34 occasions from 16 September 1982 through May 1983. During each visit 1–2 observers searched the facility for any evidence of bird mortality. Although searches were not conducted in a fixed pattern, the entire facility was covered during each visit. Bird carcasses were readily found because of the sparse vegetation and level ground of Solar One. Experiments involving the placement of 19 bird carcasses of various species within and just outside (<200 m) the fenced facility were conducted in May and September 1982 to measure the rate of bird carcass removal by scavengers. These carcasses were checked periodically until removed by scavengers or decomposed.

FIGURE 1. Aerial view of Solar One: (A) heliostat field, (B) central receiver tower, (C) evaporation ponds. Tower height = 86 m, diameter of field = 765 m.

To determine the impact of bird mortality on local populations, 1–2 observers conducted surveys of relative avian abundance within an area of approximately 150 ha surrounding Solar One, concentrating on the facility grounds (32 ha), evaporation ponds, and agricultural fields. These surveys were conducted on at least 2 d per visit for 3–4 h/d.

RESULTS

Solar One related animal mortality.—During approximately 40 wks of study, we documented 70 bird fatalities involving 26 species at Solar One (Table 1). The mean rate of mortality between visits was 1.7 birds ± 1.8 SD (n = 40, range 0–7). Results of the scavenger bias experiments indicate that from 10–30% of carcasses were removed between searches, thus, the actual rate of mortality may have been from 1.9–2.2 birds. Two causes of avian mortality were identified at Solar One, colliding with structures and burning from standby points.

The most frequent form of avian mortality was from collisions with Solar One structures. We documented 57 (81%) bird deaths (20 species) from collisions (Table 1). In most cases the cause of death was determined by the presence of broken bones (usually mandibles or wings) found through external examination. From the location of birds in relation to structures, most (>75%) died from colliding with the mirrored heliostats, although a dead Blue-winged Teal (*Anas discors*) with a broken wing was found on a platform of the receiver tower. On one occasion

Total	13	Total	57

in May 1982 a Solar One employee observed 4 Mourning Doves (*Zenaida macroura*) die in a collision with a single heliostat.

Thirteen (19%) birds (7 species) died from burning in the standby points (Table 1). Although we never observed a bird fly through one of the standby points, the heavily singed flight and contour feathers indicated that the birds burned to death (Fig. 2). Six (46%) of these fatalities involved aerial foragers (swifts and swallows) which are apparently more susceptible to this form of mortality because of their feeding behavior. Three of these aerial foragers died during a 2-wk period in May 1982, corresponding with the presence of the highest numbers of swifts and swallows observed (>500 per d), and an extensive period of heliostat testing when the occurrence and intensity of standby points was probably greater than at other times.

Relative avian abundance.—During 102 d from May–June 1982 (18 d) and September 1982–May 1983 (84 d), we recorded 107 bird species (daily mean = 16.7 ± 6.1 SD, n = 102) in the immediate area (150 ha) of Solar One. The mean daily count for individuals was 314 ± 203 SD (range 148–1040). Most avian species recorded at Solar One were migrants and only 15 species are year-round residents, with Horned Larks (*Eremophila alpestris*), European Starlings (*Sturnus vulgaris*), and House Finches (*Carpodacus mexicanus*) the most common breeding birds.

Of the habitats surveyed in this study, the evaporation ponds were the most heavily used by birds. Seventy percent of all species were recorded at least once at the ponds, and 45% were recorded only at the ponds; the majority of daily counts recorded mostly waterbirds.

DISCUSSION

Creosote bush scrub, which characterizes much of the undisturbed portions of the Mojave Desert near Solar One, is usually only sparsely inhabited by birds. The avian community of similar habitat in Arizona is usually less than 20 species (Tomoff, Ecology 55:396–403, 1974). However, we recorded 107 species in the vicinity of Solar One, 15 of which breed in the area. The special attraction of Solar One to birds is most likely related to the presence of a large, man-made water impoundment and irrigated agricultural fields, both of which produce an abundance of insects. Naturally occurring open water sources in the Mojave Desert are rare and usually ephemeral, while the man-made ponds near Solar One are permanent.

The most frequent form of avian mortality at Solar One during this study was from collisions with structures, primarily heliostats. Avian collisions are an inevitable by-product of almost all man-made structures (see Avery et al., FWS/OBS-80/54, 1980). Reflective surfaces are especially prone to collisions (Klem, Ph.D. thesis, Southern Illinois Univ., Carbondale, 1979), and it is not surprising that collisions with mirrored heliostats occur on a somewhat regular basis considering the reflective surface area of Solar One.

A form of avian mortality unique to solar central receiver power plants is burning in standby points. Death after being burned was infrequent in occurrence at Solar One, being in part a function of the frequent absence and variable intensity of standby points and the number of aerial foragers (swifts and swallows) in the airspace over Solar One.

Additional Documentation Attachment to Comment 2-F1
Attachment I-4

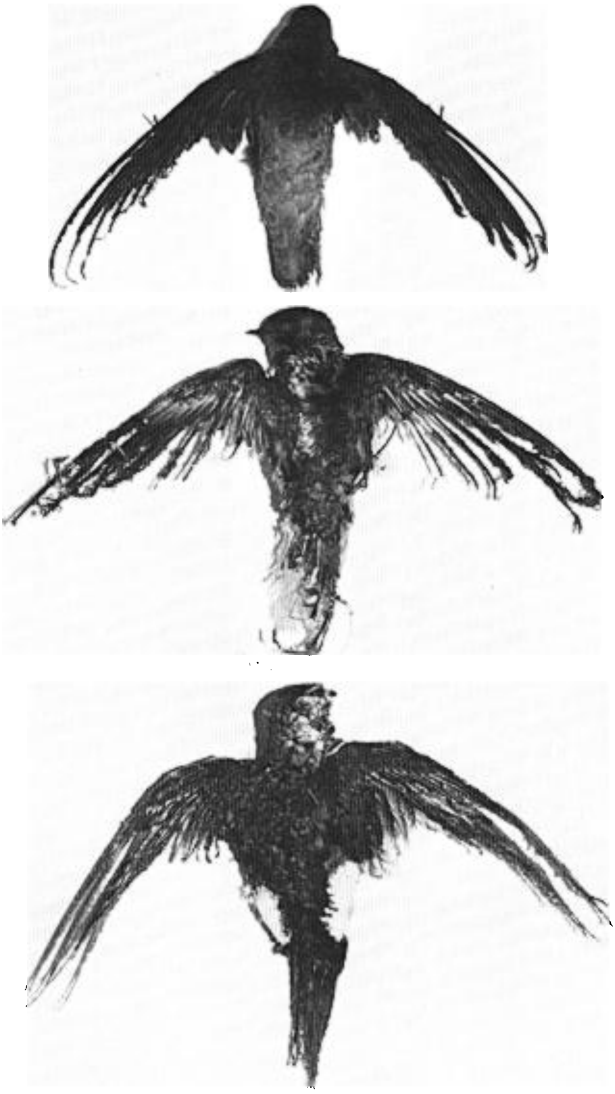

FIGURE 2. Three birds burned in standby points at Solar One. Top to bottom: Vaux's Swift (*Chaetura vauxi*), Barn Swallow (*Hirundo rustica*), and White-throated Swift (*Aeronautes saxatalis*). Note the heavily singed rectrices and remiges especially in the Barn Swallow.

Considering all known avian fatalities (70 birds) at Solar One during this study the impact of the facility on birds after construction appears minimal. Comparing the estimated rate of mortality (1.9–2.2 birds per wk) and mean relative avian abundance (314 birds per count) recorded in the vicinity of Solar One, only 0.6–0.7% of the local population present at any given time may have been affected during this study. The effect on the total population using the region in a year is obviously much less, but is unestimatable.

The results of this study suggest that, to reduce their impact on birds, future solar central receiver power plants in the Mojave Desert and other areas should not be sited in close proximity to open water or agricultural fields. The variety of species involved in avian mortality at Solar One indicates that caution should be taken when siting a solar power plant near populations of rare, threatened, or endangered species. If possible, the occurrence and intensity of standby points should be kept to a minimum. Since Solar One is only a 10 megawatt pilot facility, future projects designed to produce hundreds of megawatts will require several thousand heliostats and much taller receiver towers. The greater magnitude of these facilities may produce non-linear increases in the rate of avian mortality when compared to Solar One and extrapolations from this study should be made with caution. The removal of large tracts of desert from biological production for solar power generation and the ecological effects caused thereby should also be of concern.

SUMMARY

We studied avian mortality at an operating solar central receiver power plant in the Mojave Desert of southern California. During 40 wks of study we documented the deaths of 70 birds (26 species). The estimated mortality rate was 1.9–2.2 birds per week. Fifty-seven (81%) birds of 20 species died from collisions with Solar One structures, mainly the mirrored surfaces of heliostats. Thirteen (19%) birds (7 species) died from burns received by flying through standby points. The impact of this mortality on the local bird population is considered minimal (0.6–0.7% per wk).

ACKNOWLEDGMENTS

We thank J. Reeves (Research and Development, Southern California Edison Co.), P. Skvarna (SCE Site Manager of Solar One), D. Elliott (U.S. Department of Energy Project Director), and all other Solar One personnel for their valuable assistance on this project. P. Flanagan and G. Sawyer provided assistance in the field, and C. Barrows, P. Bloom, E. H. Burtt, Jr., J. Gore, and D. Klem provided editorial comments on the manuscript. This project was financially supported by a contract from the Southern California Edison Company to the Los Angeles County Museum of Natural History Foundation.

AVIAN CONSERVATION & ECOLOGY

Synthesis, part of a Special Feature on Quantifying Human-related Mortality of Birds in Canada

A Synthesis of Human-related Avian Mortality in Canada

Synthèse des sources de mortalité aviaire d’origine anthropique au Canada

Anna M. Calvert, *Christine A. Bishop*[1], *Richard D. Elliot*[1], *Elizabeth A. Krebs*[1], *Tyler M. Kydd*[2], *Craig S. Machtans*[2] *and Gregory J. Robertson*[1]

ABSTRACT. Many human activities in Canada kill wild birds, yet the relative magnitude of mortality from different sources and the consequent effects on bird populations have not been systematically evaluated. We synthesize recent estimates of avian mortality in Canada from a range of industrial and other human activities, to provide context for the estimates from individual sources presented in this special feature. We assessed the geographic, seasonal, and taxonomic variation in the magnitude of national-scale mortality and in population-level effects on species or groups across Canada, by combining these estimates into a stochastic model of stage-specific mortality. The range of estimates of avian mortality from each source covers several orders of magnitude, and, numerically, landbirds were the most affected group. In total, we estimate that approximately 269 million birds and 2 million nests are destroyed annually in Canada, the equivalent of over 186 million breeding individuals. Combined, cat predation and collisions with windows, vehicles, and transmission lines caused > 95% of all mortality; the highest industrial causes of mortality were the electrical power and agriculture sectors. Other mortality sources such as fisheries bycatch can have important local or species-specific impacts, but are relatively small at a national scale. Mortality rates differed across species and families within major bird groups, highlighting that mortality is not simply proportional to abundance. We also found that mortality is not evenly spread across the country; the largest mortality sources are coincident with human population distribution, while industrial sources are concentrated in southern Ontario, Alberta, and southwestern British Columbia. Many species are therefore likely to be vulnerable to cumulative effects of multiple human-related impacts. This assessment also confirms the high uncertainty in estimating human-related avian mortality in terms of species involved, potential for population-level effects, and the cumulative effects of mortality across the landscape. Effort is still required to improve these estimates, and to guide conservation efforts to minimize direct mortality caused by human activities on Canada’s wild bird populations. As avian mortality represents only a portion of the overall impact to avifauna, indirect effects such as habitat fragmentation and alteration, site avoidance, disturbance, and related issues must also be carefully considered.

RÉSUMÉ. Au Canada, de nombreuses activités d’origine anthropique entraînent la mort d’oiseaux sauvages, mais l’ampleur relative de la mortalité selon les diverses sources et leurs conséquences sur les populations d’oiseaux n’ont pas été évaluées systématiquement. Nous avons compilé des estimations récentes de mortalité aviaire au Canada causée par des activités industrielles et d’autres origines anthropiques afin de mettre en contexte les estimations calculées pour chacune des sources de mortalité présentées dans ce numéro spécial. Nous avons évalué la variation géographique, saisonnière et taxinomique de l’ampleur de la mortalité à l’échelle nationale, de même que les effets sur les populations d’espèces ou de groupes dans l’ensemble du Canada. Nous avons ensuite combiné ces estimations dans un modèle stochastique de mortalité spécifique au stade de vie. L’étendue des estimations de la mortalité par les diverses sources couvre plusieurs ordres de grandeur et les oiseaux terrestres sont le groupe le plus affecté en termes de nombre. Dans l’ensemble, nous avons estimé qu’approximativement 276 millions d’oiseaux et 2 millions de nids sont détruits chaque année au Canada, soit l’équivalent de plus de 188 millions d’individus nicheurs. La prédation par les chats et les collisions mortelles avec les fenêtres, les véhicules et les lignes de transmission ont été collectivement responsables de > 95 % de la mortalité; les sources industrielles de mortalité les plus importantes ont été les secteurs de la production d’énergie et de l’agriculture. Par ailleurs, les sources de mortalité comme les prises accidentelles par les pêcheries peuvent avoir d’importants impacts locaux ou propres à une espèce, mais ces impacts sont relativement faibles à l’échelle nationale. Les taux de mortalité variaient selon les espèces et les familles au sein des principaux groupes d’oiseaux, soulignant le fait que la mortalité n’est pas simplement proportionnelle à l’abondance. Nous avons aussi constaté que la mortalité n’est pas uniforme dans l’ensemble du pays : les sources de mortalité les plus importantes coïncident avec les foyers de population

BIRD STUDIES CANADA ÉTUDES D’OISEAUX

humaine, alors que les sources industrielles sont concentrées dans le sud de l'Ontario, en Alberta et dans le sud-ouest de la Colombie-Britannique. De nombreuses espèces sont donc vraisemblablement vulnérables aux effets cumulatifs des multiples impacts de sources anthropiques. Notre évaluation confirme aussi les grandes incertitudes liées à l'estimation de la mortalité aviaire d'origine anthropique en matière d'espèces touchées, d'effets potentiels sur le plan des populations et d'effets cumulatifs de la mortalité à l'échelle du paysage. Les efforts doivent être poursuivis afin d'améliorer ces estimations et d'orienter les actions de conservation pour minimiser la mortalité directe causée par les activités d'origine anthropique sur les populations aviaires du Canada. Puisque la mortalité aviaire ne représente qu'une partie de l'ensemble des impacts sur l'avifaune, les effets indirects – tels que la fragmentation et la perturbation d'habitats, l'évitement de sites précis, le dérangement et autres enjeux connexes – doivent également être considérés attentivement.

Key Words: *bird mortality; cats; collisions; human impacts; incidental take; industry; population effects*

INTRODUCTION

Several billion birds from over 400 species breed each year in Canada (Blancher 2002), in a wide variety of habitats. Landbirds, i.e., songbirds, raptors, upland gamebirds, represent most of the birds in Canada and tend to have large and widespread populations. Aquatic birds, such as waterfowl, seabirds, shorebirds, and inland waterbirds, occupy freshwater and marine habitats across the country. Birds occupy diverse niches across Canada that overlap substantially with human activities, and so are vulnerable to a large range of human-related stressors. The recent *State of Canada's Birds* report (NABCI-Canada 2012) highlighted conservation efforts that have contributed to increases in waterfowl and raptor populations, but shorebirds, grassland birds, and aerial insectivores have experienced rapid declines, some of which are attributed to human-driven habitat change and mortality across North America over the past 40 years (NABCI-Canada 2012).

Direct mortality resulting from human activities may have important consequences, particularly when it is additive to natural mortality, i.e. if individuals killed would have otherwise survived (Anderson and Burnham 1976). Agricultural practices, for example, have been identified as a factor in declines of Northern Pintail (*Anas acuta*; Miller and Duncan 1999, Prairie Habitat Joint Venture 2008) and Bobolink (*Dolichonyx oryzivorus*; COSEWIC 2010) as well as U.S. grassland birds (Mineau and Whiteside 2013), while reduced juvenile survivorship and population declines of urban songbirds have been linked to predation by cats (Crooks and Soulé 1999, Balogh et al. 2011). Quantification of the magnitude of human-related avian mortality, and its population-level effects on Canada's birds, is essential for directing management and conservation actions and for prioritizing future research directions (Loss et al. 2012); especially when considered in conjunction with indirect stressors such as habitat alteration and climate change.

Preventing and minimizing human-related mortality to birds, their nests, and eggs is widely supported by environmental legislation in Canada. Federal and provincial governments are responsible for the protection, conservation, and management of birds under the federal Migratory Birds Convention Act (S.C. 1994, c. 22), the federal Species at Risk Act (S.C. 2002, c. 29) and various provincial wildlife Acts. These laws generally prohibit the destruction of nests and eggs, and the "take" or killing of individual birds. Permitting systems exist to manage direct mortality due to hunting or while preventing damage and danger to the public, but provisions or systems to authorize inadvertent destruction of nests or birds as a consequence of anthropogenic activities, often called 'incidental take,' are applicable only to limited species or circumstances. Activities that may destroy nests or birds are currently managed through compliance promotion and by providing relevant information, e.g., timing of breeding seasons, key migration periods and pathways, to industrial sectors. This information allows the development and adoption of measures that minimize the risk of inadvertent destruction of nests and eggs, or killing of individuals.

Some sources of human-related avian mortality are well-quantified, such as the regulated sport harvest of game birds, but the magnitudes of most sources are imprecise or unknown. In particular, those affecting a few birds at a time, e.g., cat predation or building collisions, may often be overlooked because their local effects are rarely extrapolated nationally. Therefore, the number of birds killed annually in Canada as a result of human activities is poorly known, as are any resulting effects on populations. Despite limitations imposed by small-scale studies, nonrandom sampling designs, and an absence of experimental controls (Loss et al. 2012), preliminary estimates of human-related bird mortality at national- or continental-level scales can be highly informative. For instance, mortality from collisions with communication towers results in a total annual kill across the U.S. and Canada of about 6.8 million birds (Longcore et al. 2012), include disproportionately large impacts on certain species, many of conservation concern (Longcore et al. 2013). These studies can further highlight the susceptibility of particular bird groups to certain mortality sources, such as the vulnerability of long-distance or nocturnal migrants to collisions with towers and buildings (Klem 2009, Manville 2009, Arnold and Zink 2011) or of auks to bycatch in gill nets (Piatt et al. 1984).

The papers presented in this special feature of *Avian Conservation and Ecology* reflect the current scientific understanding of the magnitude of human-related bird mortality in Canada, based on data collected from a variety of industrial and other activities. Each paper reports an estimate of the total annual loss of birds, nests, or eggs, and considers the likelihood of population-level effects on species in Canada. In this synthesis, we compare the relative contribution of each source of mortality, including several estimates that are unpublished or were published recently elsewhere, and consider the implications of the total kill from all sources. Specifically, this synthesis aims to (i) identify, quantify, and compare sources of human-related avian mortality in Canada, (ii) explicitly model the sources of uncertainty in the mortality estimates, (iii) identify the remaining gaps in the current knowledge of threats to Canadian bird populations, and (iv) thereby help to prioritize research, policy, management, and conservation actions aimed at understanding and reducing human-related bird mortality in Canada.

METHODS

Sources of mortality

We synthesized estimates of the magnitude of human-related avian mortality in Canada from major industrial sectors and nonindustrial or public activities that we believe kill substantial numbers of birds. Initial estimates were developed in a series of reports prepared for Environment Canada. Nine of these are found in this special feature, namely mortality caused by: collisions with vehicles (Bishop and Brogan 2013), cats (Blancher 2013), marine industries, i.e., offshore oil and gas, commercial fisheries (Ellis et al. 2013), commercial forestry (Hobson et al. 2013), collisions with windows in buildings (Machtans et al. 2013), collisions with power transmission lines (Rioux et al. 2013), mechanical agricultural activities such as haying or mowing, cultivation, and harvest (Tews et al. 2013), terrestrial oil and gas (Van Wilgenburg et al. 2013), and wind power (Zimmerling et al. 2013). Estimates from communication towers appear elsewhere (Longcore et al. 2012). Reports on several other anthropogenic activities with more limited data are cited here as unpublished works (roadside maintenance: D. Abraham, D. Pickard, and C. Wedeles, *unpublished manuscript*; agricultural pesticides: P. Mineau, *unpublished manuscript*; mining: J. Williams, *unpublished manuscript*; electrical and hydro power generation: J.-P. L. Savard and S. Rioux, *unpublished manuscript*; Appendix 1). Unless otherwise specified, the information for each source presented in this synthesis is drawn directly from these papers and reports.

Published mortality estimates for three other activities are also presented for comparison. Sport-hunting totals for migratory game birds in Canada from years 2000-2011 were obtained from the National Harvest Survey data base (http://www.cws-scf.ec.gc.ca/harvest-prises/def_e.cfm). Data on total annual harvest of nonmigratory game birds, mainly Galliformes, were obtained from provincial and territorial government web sites and representatives. We also include an estimate of seabird mortality from chronic ship-source oil pollution in the northwest Atlantic from the late 1990s (Wiese and Robertson 2004).

We were unable to include several additional sources of human-related mortality that may be important to Canadian bird populations. A recent assessment of livestock impacts (B. Bleho, N. Koper, and C. S. Machtans, *unpublished manuscript*) found both positive effects of vegetation management and negative effects of trampling on bird nests, estimating a loss of ~1.5% of nests at a local scale, but is not included here because it did not quantify total mortality. We also did not calculate mortality and nest destruction from forest harvesting on private lands. Canada's National Forestry Database (http://nfdp.ccfm.org) indicates that private land harvest accounts for ~19% of the total annual volume of wood harvested from all lands in Canada, but we did not assess whether harvest timing or bird densities were similar to those calculated for commercial harvest. We found little published information on the magnitude of avian mortality in Canada from aircraft-strikes, and impacts from large-scale tailings ponds remain uncertain (Timoney and Ronconi 2010), although the number of birds killed annually by these sources is expected to be small. Recent evidence also indicates potentially important population-level effects of rodenticides on birds of prey (Thomas et al. 2011), but this source of mortality was not considered here. Effects of the aquaculture industry were initially assessed because entanglements with exclusion nets or nets associated with farms are potential sources of mortality (Price and Nickum 1995). However, this mortality source has not been documented in Canada, and the consensus was that aquaculture currently causes very limited direct bird mortality. Information on indirect impacts of aquaculture development on marine bird populations is also limited, and shellfish aquaculture may sometimes benefit certain waterfowl species (Zydelis et al. 2006, 2009). As a result, aquaculture is not considered further. Finally, we do not include estimates of bird bycatch in freshwater fisheries although the documentation of large kills suggests this is an important information gap (e.g., Ellarson 1956).

Comparing mortality estimates between sources

Human activities can affect birds at different stages of their annual cycles. Activities that alter habitat during the breeding season, such as forestry and agricultural mowing, tend to destroy nests, eggs and young. Many other sources cause direct mortality of breeding adults, subadults, and juvenile birds, such as fishing or collisions with cars or buildings. We present total mortality estimates by the life stage where it occurs, to highlight differences among sources.

We used the methodology of Hobson et al. (2013) and Van Wilgenburg et al. (2013) to develop a stochastic simulation model that expresses stage-specific losses as an equivalent loss of potential adult breeders. This enabled a comparison of the effects of mortality affecting species at different life stages. In addition to allowing comparison of mortality across sources, this model explicitly quantified and combined the various sources of uncertainty in current mortality estimates. An advantage of this modeling approach is that it allowed us to combine data with various measures of central tendency and spread (means, medians, min-max ranges, confidence limits). These modeled values were also used to assess population-level effects of mortality.

The stochastic model controlled both for effects at differing life stages and for variation in life history strategies by converting all individuals to the potential breeding adult stage. However, we were unable to control for variation in time needed to reach those stages because longer lived and low-fecundity species take longer to reach breeding age, making populations slower to recover from perturbations. Our analysis also did not assess the effects of activities reducing future productivity through habitat loss or alteration, e.g., unreclaimed oil and gas clearings in forest, which may be a significant consequence of some of the industrial activities considered here. Our analysis does enable direct comparisons of mortality across various sources, which should be most reliable when focused on comparisons of sources that affect groups of species with similar life history characteristics. Most importantly, these comparisons of numbers killed do not take into account differences in population sizes of species, or species groups.

Stochastic model to derive estimate of potential adult breeders killed

Converting estimates of stage-specific losses to potential adult breeders using the stochastic model involved the following steps. First, we compiled estimates of stage-specific mortality (nest, egg/nestling, or independent bird) for each mortality source, including any information on age-composition (for independent birds killed) and species-group composition of the kill (see Appendix 2 for details). Additional author feedback was sought for some sources, especially regarding estimates of approximate species-group or age composition of the kill.

Next, unless exact values were available, probability distributions were assigned to all values for stage-specific kill totals, age-ratios, and species-group composition (see Appendix 2, Table A2.1). Kill totals from individual papers generally included some measure of central tendency (mean, median, or midpoint) and data spread (confidence interval or min-max range) that were converted to values required to model a log-normal distribution (mean μ and standard deviation σ). We modeled kill estimates as log-normal distributions because these estimates were all based on some multiplicative extrapolation. Age-ratios were modeled in various ways; draws from a binomial distribution were used when proportions were reasonably well known, beta distributions were used when estimated variances in proportions were available, and uniform distributions were used when only minimum and maximum values were reported. Similar distributions were used for species-group proportions, except that multinomial distributions were used when more than two species-groups were affected. For sport harvest of migratory birds, detailed data on age-ratios of the kill were available for ducks, geese, and shorebirds (snipe and woodcock), and age-ratio data for snipe and woodcock were applied to other species (doves, pigeons, rails, and cranes). Age-ratios were not needed for the harvest for upland nonmigratory game birds (Galliformes), because juvenile and adult nonbreeding season survivorship probabilities are comparable for these birds. Age at first breeding was assumed to be the second year of life for all species groups except seabirds, which were assumed to breed in their fifth year.

Demographic rates, with associated measures of data spread where available, were collated for each species group; these included clutch size, nest success, hatchability (or hatch success), survival of young to fledging, overwinter survivorship of juveniles, and adult survivorship. Note that in some instances only the product of several parameters was available, e.g., a general productivity value that equaled clutch size × hatching success × survival of hatchlings to fledgling (see Appendix 2, Table A2.2). For landbirds, except nonmigratory game birds, we used the values already collated in Hobson et al. (2013), with adult survival rates obtained from Johnston et al. (1997). All other demographic rates were obtained from literature values for species considered representative of each species group (Appendix 2, Table A2.2). For shorebirds, we chose values from two larger bodied upland nesting species, as these species are more likely to be affected by the mortality sources considered, i.e., mowing and collisions, compared to smaller Arctic-breeding migrants. When a particular value was not available, notably overwinter survival of hatch-year birds (S_o), this value was estimated using the other vital rates available, assuming a stable population ($S_o = (1- S_a)/F$), where S_a is adult survival and F is fecundity (number of independent young produced). A variety of distributions was used to model these vital rates. For instance, beta distributions were used for well-estimated parameters, draws from uniform distributions were used when uncertainty was high and only minimum and maximum values were available, and random draws from a collection of rates were used for landbirds and shorebirds where a number of estimates were available. See Appendix 2 for additional details on vital rates used for each species group.

Finally, these values and distributions were used to estimate the equivalent number of potential adult breeders that would be removed from the population, based on the stage-specific kill estimates. For example, for an activity that kills eggs and nestlings at the start of the breeding season, draws from the distribution of total kill of eggs for a given species group were multiplied by draws for estimates of nest success, hatch success, survival of young to fledging, and overwinter survival for that species group. Models were run 100,000 times, and various descriptive statistics of the resulting distributions were extracted. We present medians with 90% intervals, to allow direct comparison of the numbers presented for forestry (Hobson et al. 2013) and terrestrial oil and gas (Van Wilgenburg et al. 2013). Note that no conversion was necessary for these two sectors because the authors directly converted their estimates of nest losses to the equivalent loss of potential adult breeders.

Extent, scale, and scope of mortality

We tabulated the season when most human-related mortality occurs (spring, breeding, fall, winter) in Canada for each of the main groups (landbirds, seabirds, shorebirds, waterbirds, waterfowl) to better understand the timing and extent of mortality across Canadian bird populations. We assigned a qualitative score of ‘no/little known effect,’ ‘some effect,’ or ‘large effect’ to each source/group/season combination, based on the information in each paper or report and feedback from their authors. Generally, a ‘large effect’ score was assigned when a particular species group was clearly identified as being frequently killed during a given season, whereas ‘some effect’ was assigned to species groups and seasons that were peripherally affected. Note that factors that kill birds while they are outside of Canada, including human-caused mortality to migrants, were not included in this assessment.

To quantify the relative population impact of differing sources of human-related mortality (hereafter ‘population-level impacts’), we compared the estimated mortality to the total abundance of individual populations, species, or families where data were available at that resolution; in some cases, mortality data were not available below the level of broad taxonomic group. For wind power, marine industries, oil and gas, agriculture, and roadside maintenance, we present population-level impacts that were directly calculated by the paper or report authors; for building collisions, we calculated family-level impacts by combining kill data provided by authors with current estimates of family-level abundance in Canada (Blancher 2002; P. Blancher *unpublished data*). For all these estimates, total kill of nests/eggs/nestlings was converted to the equivalent mortality of potential breeding adults, as described above, to enable comparability among sources of mortality; see Appendix 3 for full details on population-level kill and abundance. Note that although population-level impact estimates provide examples of the relative importance of particular mortality sources, these populations do not represent a random sample of all population-level impacts because they may have been highlighted by authors for different reasons, e.g., those considered particularly at risk, those representative of most birds affected, or those with the best available data on population size. We considered reference levels of 10%, 1%, and 0.1% to be informative. Individual sectors near or above 10% could likely translate to detectable negative population effects. Population proportions of 1% are considered nationally significant from the perspective of management of protected areas (e.g., RAMSAR criteria). We are not aware of documented population effects for rates of mortality below 0.1% from individual sources.

Spatial assessment of mortality risk

A spatial representation of cumulative human-related mortality in Canada was created for a subset of sectors. Applicable or proxy spatial information was available for the following eight sources of terrestrial-based mortality: cats, bird-window collisions, bird-vehicle collisions, bird-communication tower collisions, agriculture (haying and crops), commercial forestry, oil and gas, and wind turbines. All data were summarized and displayed on a 50 × 50 km tile grid covering Canada. This grid-level balanced the goal of providing interpretable images against the false precision of mapping data that usually had low spatial resolution or concordance with specific processes causing mortality, e.g., we know precisely where all paved roads are, but not where bird-vehicle collisions occur on those roads. All data sources and detailed procedures used to derive the maps are provided in Appendix 4.

We began by taking the proportion of activity in a 50 × 50 km tile grid across areas of resolution defined by the original research paper, e.g., provincially for forestry; by turbine for wind facilities; and by applicable portions of Bird Conservation Regions for agriculture. The total mortality estimate for each tile was then calculated by multiplying the proportion of activity in each tile by the original mortality estimate (number of wind turbines, km^2 of oil and gas activity, etc.). The completed tiles from the eight sources were overlaid and summed to compute the total mortality estimate per tile.

The final map was colored using 10 classes calculated by the Jenks classifier (Jenks 1967) in ArcGIS 10 and output in raster format. We applied a low-pass filter to the raster output using a 5 × 5 tile kernel size (Jensen 2005). We caution that the map represents an index of probable mortality across key sources, and is only an approximation. Accurately mapping mortality would require spatially explicit information on bird density, specific details on how and when each sector interacts with birds in each tile, and a variety of covariates that are not available nationally or may not be understood, e.g., why does mortality at tall buildings apparently differ appreciably among cities (Machtans et al. 2013)?

RESULTS

Total mortality estimates

Mortality estimates from each human-related source ranged from a few thousand to tens or hundreds of millions of birds.

In Canada, all combined sources of human-related mortality destroyed an average of ~2 million nests and killed ~269 million birds per year, or the equivalent of ~186 million potential adult breeders each year (Fig. 1). Cats and collisions with structures were the largest causes of human-related bird mortality in Canada: cumulatively, the top five sources of mortality, i.e., predation by feral and pet cats, and collisions with road vehicles, houses, and transmission lines, represented more than 95% of the individuals killed across all human-related sources. Because each of these top-ranking mortality sources are widespread, they may represent relatively small numbers at the local scale, but sum to very high levels of mortality when extrapolated across Canada. In contrast, some other mortality sources do not occur uniformly across the country, e.g., terrestrial oil and gas, fisheries, or are from industries located at relatively few scattered locations, e.g. wind power, and thus have relatively modest national-level kill totals, despite measurable localized effects.

The nine largest sources of anthropogenic mortality all killed mobile individual birds, including adult, subadult, and juvenile birds, although over a million nests and eggs are destroyed annually by forestry and agriculture, respectively (Fig. 1A). Fig. 1A and Table 1 show the total number killed by each source, identifying the life stage at which most mortality occurs, i.e., nest destruction, mortality of eggs or nestlings, or loss of independent mobile individuals. Mortality occurring at two stages, i.e., loss of eggs and mobile individuals through road maintenance, is shown as two points for that source. Note that although most estimates were made at a national level, for example, by extrapolating from local-scale estimates across the country, a few were only made at smaller scales (indicated as hollow symbols in Fig. 1): the agricultural haying and road maintenance estimates each represent impacts on just five and six focal species, respectively, and the hydro reservoir estimate was made for Quebec only. Total Canada-wide cross-taxa mortality caused by these activities is therefore likely to be appreciably higher than the values presented here.

The relative ranking of mortality sources was similar for the stage-specific and converted values (Figs. 1A, 1B), particularly for the largest sources of mortality. However, for human activities that destroy eggs and nests, the equivalent potential adult breeder total was considerably reduced, and thus the relative ranking of these sources somewhat altered, because many of the eggs or young killed by these sources would have not been expected to survive to adulthood otherwise (Fig 1B).

Converted estimates pooled across related activities provided broad estimates for the main sources of human-caused mortality (Fig 1C). These pooled sectors were cats (feral and pet), transportation (vehicle-collisions, road maintenance, and chronic ship-source oil), buildings (collisions with all three types), electrical power (transmission-line collisions, hydro reservoirs, electrocutions, transmission-line maintenance, and wind energy), harvest (migratory and nonmigratory game birds), agriculture (haying and pesticides), fisheries (all gear types), oil and gas (all terrestrial and marine sources), and mining (pits/quarries and metals/minerals); the original single-source values for forestry and communication towers are also shown. Nonindustrial activities (cats, transportation, and buildings) still represented the greatest overall sources of mortality, while electrical power and agriculture represented the largest industrial sources of mortality, with an annual kill of over 18 million and over 2 million potentially breeding birds, respectively. At the other end of the spectrum, the fisheries, oil and gas, and mining industries each killed the equivalent of fewer than 25,000 breeders annually (Fig. 1C). Note that within sectors, some sources of mortality were relatively low, e.g., electrocutions in the electrical power sector, while others dominated the overall sectoral kill, e.g., transmission line collisions.

Evaluating potential population effects: seasonal and taxonomic distribution of mortality

The distribution of anthropogenic mortality among bird groups and across seasons for each mortality source showed that landbirds as a group were affected by the widest range of human activities (Table 2). These impacts occurred primarily during the breeding seasons, as expected, because many species overwinter outside of Canada. Shorebirds and waterfowl also faced many potential threats at their nesting sites, and birds across all groups confronted a range of human-caused mortality during spring and fall migration, particularly from collisions with cars, buildings, power-lines, and transmission structures.

Landbirds make up the majority of all Canadian breeding birds, and they constituted most of the estimated total mortality among the five species groups when expressed in common units of potential adult breeders (Table 3). In total, we estimated that 89% of all birds killed annually by human activities are landbirds; 6% are waterfowl, and the remaining 5% includes waterbirds, shorebirds, and seabirds. The majority of mortality occurred through direct kill of mobile individuals (74%; mostly cats, but see Table 2 for categories of impact type), with 25% of mortality caused by collisions. The destruction of nests represented less than 1% of overall estimated impact when converted to potential adult breeders.

Although overall national-scale mortality estimates illustrated the magnitude of bird mortality across Canada, some human-related activities had disproportionately large effects on particular species or populations, with the potential for population-level impacts at a regional or national level (Fig. 2; see Appendix 3 for full details). For example, marine fisheries bycatch had one of the lowest total mortality estimates nation-wide, but may annually kill a relatively large

Fig. 1. Annual mortality of Canadian birds due to human activities (log-scale). Panel A shows stage-specific estimates for each activity, according to whether entire nests, single eggs/nestlings, or mobile individuals were killed, as in original papers and reports. Values include both means and medians, and error bars represent both confidence limits (90% or 95%) and maximum/minimum ranges, as originally presented. Panel B shows converted mortality estimates for each activity (median with 90% confidence limits), where stage-specific kill totals have been converted to the equivalent number of potential adult breeders based on a stochastic model incorporating species-composition and demography. Hollow symbols indicate mortality only estimated for part of Canada or for a limited number of species, and thus where total Canada-wide cross-taxa mortality is likely much higher than these estimates. Panel C shows these same converted estimates (median with 90% confidence limits), pooled across related activities (cats: feral and pet; transportation: vehicle-collisions, road maintenance, and chronic ship-source oil; buildings: collisions with all 3 types; power: transmission-line collisions, hydro reservoirs, electrocutions, transmission-line maintenance, and wind energy; agriculture: haying and pesticides; harvest: migratory and nonmigratory birds; fisheries: all gear types; oil and gas: all terrestrial and marine sources; mining: both pits/quarries and metals/minerals), as well as the original single-source values for forestry and communication towers. Values in all panels are ranked in descending order according to the converted kill totals. See text and Appendix 2 for citations of papers and reports used as data sources.

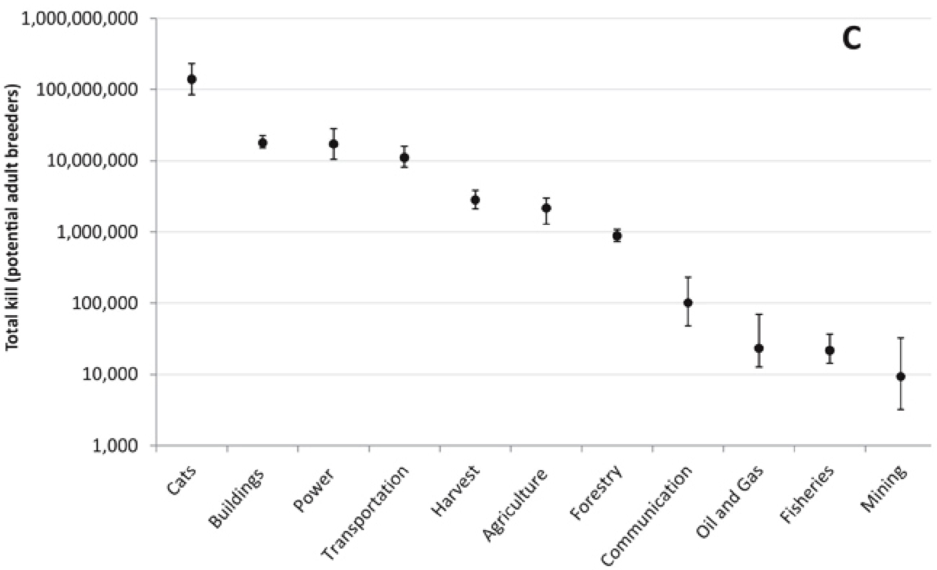
Figure 1 continued.



proportion of Canadian populations of a few species, e.g., Black-footed Albatross *Phoebastria nigripes*: 4% of the entire Canadian population, or Common Eiders *Somateria mollissima*: 7% of the Nova Scotia breeding population (Fig. 2). Mortality from building collisions also nonrandomly impacted landbirds. Overall, tall buildings killed less than 0.01% of total abundance of any landbird family, whereas between 2-5% of nuthatches, chickadees, and pigeons may have been killed at houses (see Bayne et al. 2012 for proportions of house-collision kills by family, which we used in Appendix 3 and Fig. 2). Although this simple comparison does not capture the complexity of potential population effects, it confirms that national mortality totals alone do not reflect the ecological importance of human-related activities for most species and that mortality is not simply proportional to abundance (see also Longcore et al. 2013).

We did not directly assess the impacts of sport harvest on populations of game birds because ongoing assessments exist elsewhere (e.g. Williams and Johnson 1995, Nichols et al. 2007), and extensive programs are in place throughout North America that ensure that any population-level effects of regulated harvests are sustainable in the long term (e.g., Runge et al. 2009). These impacts would likely have dominated Fig. 2, because sport-harvest was clearly important as a human-related source of mortality in Canada for waterfowl and an important factor for some other bird groups (Table 3).

Spatial distribution of mortality risk and potential cumulative effects

Human-related mortality from terrestrial sources was not uniformly distributed across Canada (Fig. 3A) because areas of higher mortality corresponded with areas of high human population and high human activity. Peak mortality for all sources combined was highest in southern Ontario and Quebec, around the five major prairie cities, and in southwestern British Columbia. In addition to having high human populations, and correspondingly large numbers of cats, buildings, and roads, numerous industries overlap with these areas. Overall, very little avian mortality from the sources that we mapped currently occurs in the northern part of many provinces and in the territories.

The distribution of mortality when excluding the three largest sources (cats, buildings, roads) was spread more evenly across southern Canada (Fig. 3B), partly reflecting broad areas of forest harvesting and the diffuse distribution of communication towers across this area. Southern Alberta and southeastern Ontario appeared to be areas for potential additive effects of multiple industries. The high values in the Maritimes were partially attributable to forestry, whereas those in the lower mainland of British Columbia primarily reflect the high number of hay farms. Individual, unsmoothed maps for each mortality source are provided in Appendix 4.

In contrast to most impacts of clearing activities (Fig. 3B), collision-based sources of mortality impacted some species more than others, and thus potential cumulative effects were harder to assess spatially. Based on available data, we found indications that different types of collisions appeared to affect different groups of landbirds. At the family level, warblers dominated birds killed in communication tower collisions (15 of the most abundant 20 species recorded, Longcore et al. 2013) whereas a wider variety of species dominated tall

Table 1. Life stage-specific (nests, eggs/ nestlings, or independent individuals) mortality estimates of human-related avian mortality in Canada derived directly from published papers and unpublished reports. These values are illustrated in Fig. 1A, and served as the basis for the stochastic model conversion to an equivalent number of potential adult breeders; mortality sources are listed in descending order of converted kill totals. Characteristics of the estimate are indicated in the last column, i.e., whether central values were mean, median, or midpoint of a range, and whether lower/upper values represent a confidence interval (CI) or a range. Note that the estimates for forestry and terrestrial oil and gas shown here represent the estimated number of nests destroyed.

Fig. 2. Proportion of population affected by anthropogenic mortality on Canadian birds, by species group (panel A) and by mortality source (panel B), for populations where data were available at sufficient resolution. Estimated annual kill for a given species, population, or family (converted to potential adult breeders) is plotted against the estimated Canadian abundance for that group, to show the estimated proportion of the total population killed by each activity. The three diagonal lines represent a mortality rate of 10%, 1%, and 0.1% for visual reference and are explained in more detail in the text. Details of mortality and abundance totals, as well as the identity of the species/population/family represented by each data point, are provided in Appendix 3. Game bird harvests are not included in this figure because they would dominate the figure and this source of mortality is regulated.

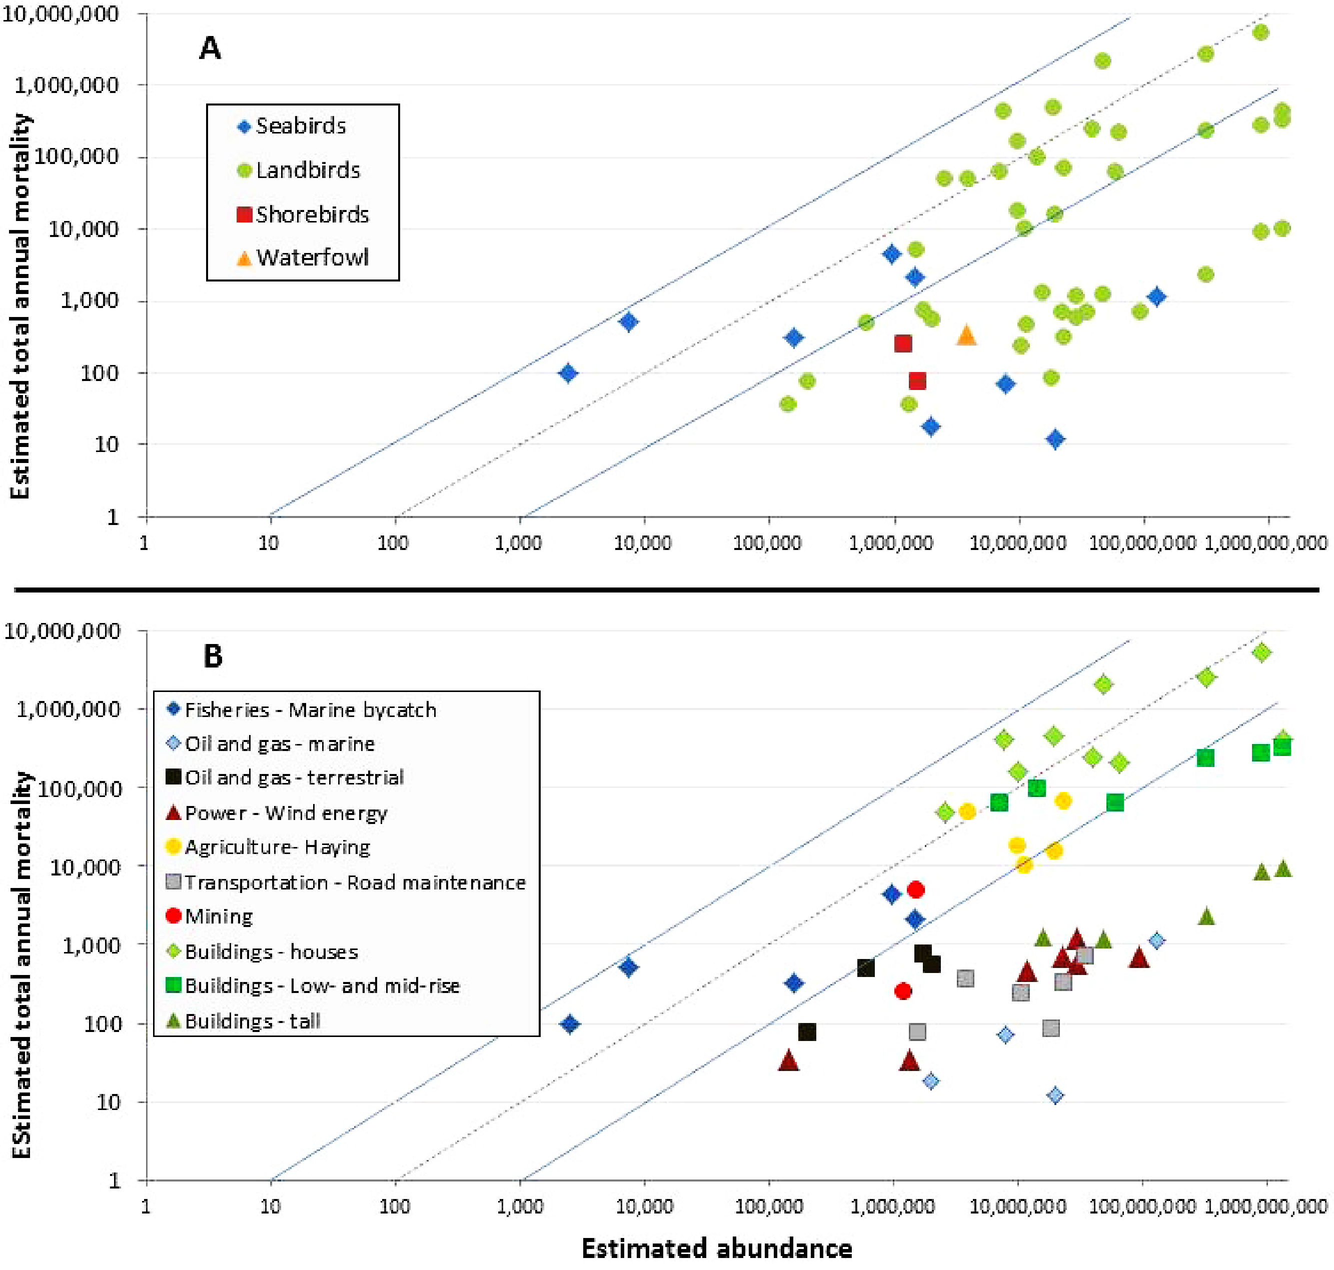

Fig. 3. Approximated distribution of total bird mortality estimates in Canada from eight terrestrial sources (cats, building collisions, vehicle collisions, agriculture, forestry, terrestrial oil and gas, communication towers, and wind turbines). Panel A is the sum of all eight sources, while panel B excludes the first three in the above list. These maps present the probability of mortality based on the distribution of each source in Canada. The hotspot on Montreal is because a single tile of our grid overlapped that city perfectly, while, for example, Toronto was centered at the intersection of 4 tiles. Unsmoothed maps for each mortality source and all mapping methods are provided in Appendix 4.

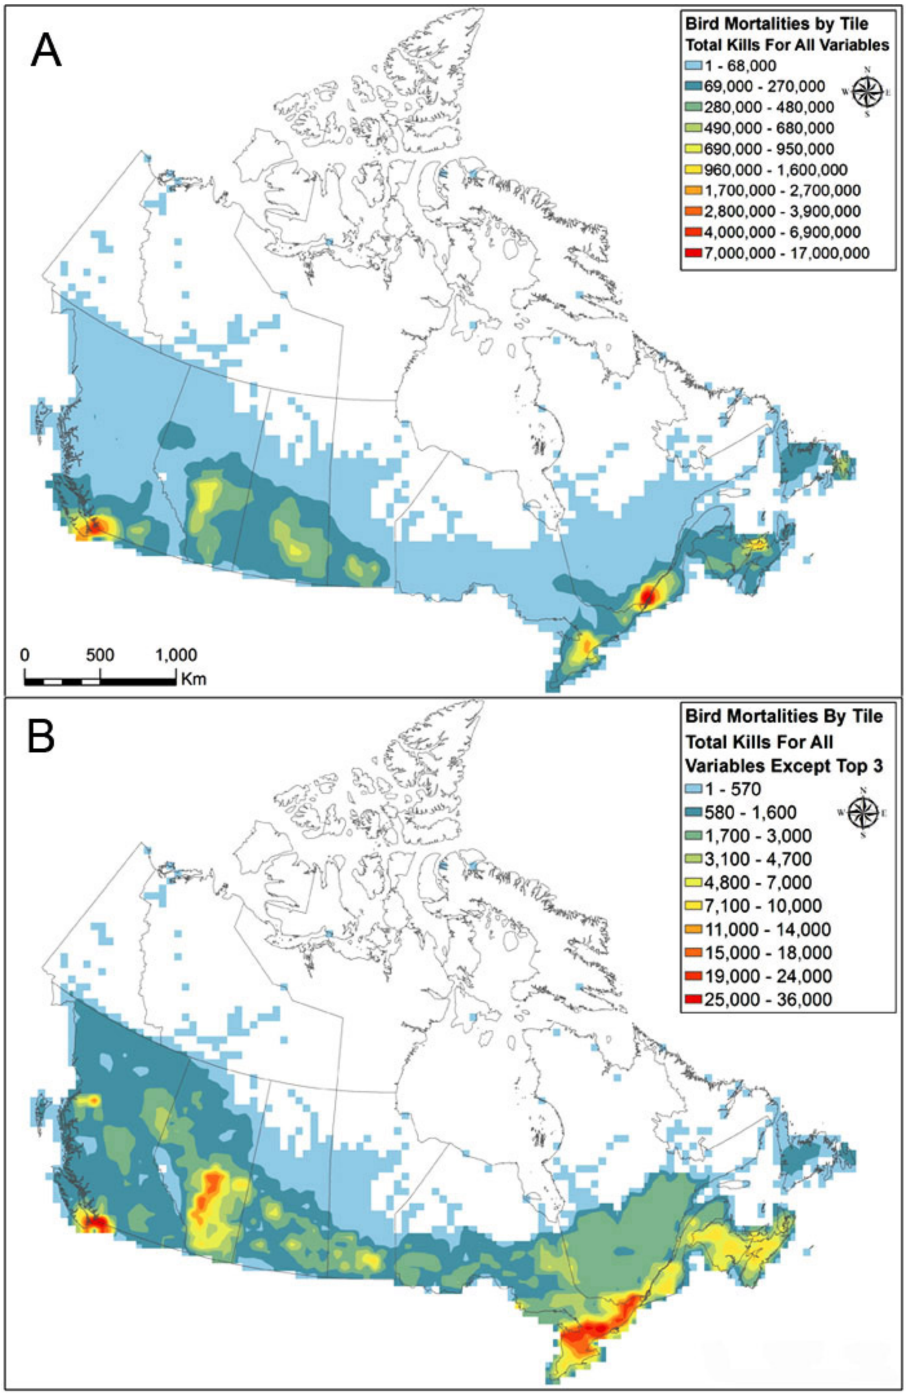

Table 2. Seasonal and species-group breakdown for each source of human-related avian mortality in Canada: o little or no known effect, + some effect, including effects anticipated but not quantified [highlighted yellow], ++ large effect [highlighted orange], na not applicable. Within the effect-type categories (collisions, direct kill, or nest destruction), mortality sources are ordered in descending order of converted kill totals, as presented in Fig. 1B. Comparisons should be made within source rows, rather than within columns because the level of effect was evaluated qualitatively among seasons and species-groups within each source, and is not intended to reflect differences in magnitude among sources. Note that ‘winter’ refers only to impacts on birds while wintering in Canada.

[†] mortality from both direct kill and collisions;
[‡] mortality from both nest destruction and direct kill

building collisions (only 6 of the top 20 were warblers, Machtans et al. 2013). At the species level, the top five species killed in tall building collisions in southern Ontario (based on the Toronto Fatal Light Awareness Program, www.flap.org) were Golden-crowned Kinglet (*Regulus satrapa*), White-throated Sparrow (*Zonotrichia albicollis*), Ruby-crowned Kinglet (*Regulus calendula*), Dark-eyed Junco (*Junco hyemalis*), and Ovenbird (*Seiurus aurocapilla*), together comprising 42% of mortalities. In contrast, the top five species killed in communication tower collisions in the Bird Conservation Region, which includes Toronto (Longcore et al. 2013), were Ovenbird, Ruby-crowned Kinglet, Blackpoll Warbler (*Setophaga striata*), Red-eyed Vireo (*Vireo olivaceus*), and Common Yellowthroat (*Geothlypis trichas*), together comprising 44% of mortalities. Species reported killed most often at wind-turbines only showed some overlap with these other collision-sources, with the top five being Horned Lark (*Eremophila alpestris*), Golden-crowned Kinglet, Red-eyed Vireo, European Starling (*Sturnus vulgaris*), and Tree Swallow (*Tachycineta bicolor*; Zimmerling et al. 2013). Only 80% of birds killed at wind turbines were passerines, proportionately much lower than at communication towers (97% passerines, Longcore et al. 2013) or in collisions with windows of tall buildings (90% passerines, Machtans et al. 2013). Much better species-level data are required concerning cat kills and window collisions at homes, as well as from the range of other human activities for which population-level data are not yet available, to better understand the most significant population impacts and to identify additive or cumulative impacts. Even the species comparisons above should be taken with caution because the spatial scale of the data sources differ across each study.

Table 3. Median annual estimates of human-related mortality in Canada across the five major species groups, based on a stochastic model that converted stage-specific mortality to potential adult breeders, ranked in descending order according to total estimated mortality across all bird groups. Note that species-group totals do not sum exactly to the ‘all birds’ value because uncertainty in species composition was explicitly modeled and the “all birds” value was modeled independently of each species group’s total. See text and Appendix 2 for details of the stochastic model conversions. In cases where mortality was not fully extrapolated to all regions and taxa, e.g., where it was only estimated for a given region or set of focal species, the taxonomic or regional scope of the estimate is indicated; impacts estimated Canada-wide and across taxa are indicated as ‘all’ in the Scope column.

DISCUSSION

Interpreting mortality estimates

Human-related activities inadvertently kill hundreds of millions of birds and destroy millions of nests in Canada every year, with landbirds most affected. Birds are primarily affected during the breeding season, although collisions occur year round. Landbirds were subject to the largest diversity of impacts, suggesting that they may be most vulnerable to additive effects across sources and seasons. Many of these human-related activities also pose a threat to migrants when outside of Canada, mortality that has not been quantified here, and thus the cumulative year-round population-level effects will be higher for species that migrate outside Canada. For instance, in the United States a median estimate of 2.4 billion birds are killed annually by cats (Loss et al. 2013), and a substantial proportion of these birds will have been produced in Canada. In the context of severe population declines already observed for many groups (e.g. long-distance migrants: BirdLife International 2008; grassland breeders, shorebirds, aerial insectivores: NABCI-Canada 2012), human-related activities create additional population pressures for many of Canada’s birds.

The estimated number of potential breeders killed annually by specific sectors or sources differs by several orders of magnitude, ranging from fewer than one thousand for routine marine oil and gas activities, to tens of millions for collisions with vehicles, transmission lines, and houses, and over 140 million for cat kills. Most of these activities are known to effect birds at a local scale, although extrapolation to the national level has highlighted the magnitude and potential significance of several widespread impacts, such as cats and building collisions. For other activities, a national scale perspective may lead to important local-scale mortality being overlooked, e.g., regionally concentrated fisheries bycatch. Our geographical assessment revealed the highest cumulative risk to birds in regions of high human population density and related road networks. Southern Alberta and Ontario also stood out as areas with potentially high cumulative effects because of a convergence of several human activities in addition to the top three sources, whereas other high risk locations were generally attributable to single mortality sources.

Although these estimates provide new insight into the relative significance of different industrial and other human-related activities to wild birds in Canada, the precision of our review is limited by the availability of relevant information from Canada. The wide confidence ranges around the converted estimates explicitly indicate the considerable uncertainty in our present knowledge of the magnitude of source-specific mortality, so these should be viewed as preliminary estimates pending further refinement, additional research, and increased monitoring and assessment.

Uncertainties and caveats

Accurate estimation of the magnitude of bird mortality from industrial and other human-related activities is compromised by the need to estimate large-scale national impacts by extrapolating from small studies, often with limited data. Wherever possible, authors directly accounted for known sources of bias, such as variability in detection and scavenging of bird carcasses (e.g., road vehicles: Bishop and Brogan 2013; building collisions: Machtans et al. 2013; wind power: Zimmerman et al. 2013; transmission line collisions: Rioux et al. 2013). Some explicitly assessed the sensitivity of mortality estimates to key parameters such as the number of unowned cats in Canada (Blancher 2013), or the timing of agricultural or oil and gas activities in relation to breeding seasons (Tews et al. 2013, Van Wilgenburg et al. 2013). Overall, we consider that the estimates presented in this issue are likely to be precise to within an order of magnitude, particularly because actual levels of mortality from each source will likely vary significantly from one year to the next.

Some important sources of estimation bias still remain. For instance, the scale of available data may sometimes be mismatched to the scale of human-related activities. The harvest volume from commercial forestry activities is typically reported provincially and not by area cut, while the density of nesting birds is inferred from extrapolating local-scale point-counts to Bird Conservation Regions, which do not align with provincial boundaries (Hobson et al. 2013). Additionally, specific Canadian data for predation rates by cats, pesticide use, and mortality from power generation were also lacking (Blancher 2013; Appendix 1), so the estimates presented here are derived in part using data from other countries or continents. Extrapolations for marine oil and gas were based on untested assumptions, with few data available to inform these estimates (Ellis et al. 2013).

Estimates of effects from most sources could be improved by a better understanding of the seasonal distribution of mortality. For instance, the proportion of industrial activities that occur within the breeding season had to be approximated for several sources (e.g., forestry: Hobson et al. 2013; oil and gas: Van Wilgenburg et al. 2013). Species-composition of the kill is also poorly known for many human activities (e.g., vehicle collisions: Bishop and Brogan 2013; transmission line collisions: Rioux et al. 2013), limiting our ability to evaluate potential population-level impacts. Finally, most analyses presented here were designed to estimate direct annual kill of individual birds or destruction of nests. Estimates for most mortality sources that also involve significant clearing or alteration of habitat do not reflect the total long-term impact of the activity on bird populations because most analyses did not account for additional long-term impacts, e.g., via habitat change (Wells et al. 2008) or related one-time mortality events, e.g., destruction of nests during initial construction of transmission lines (Rioux et al. 2013).

The stochastic simulation model addressed some of these biases, so that the distributions of potential adult breeder mortality are more likely to reflect the actual impacts of estimated mortality. The confidence limits around median estimates reflect the remaining uncertainty in the input values; for instance, the magnitude of mortality caused by fisheries bycatch or wind power is known with greater precision than that caused by mining activities or terrestrial oil and gas. These estimates all assume that most mortality estimated here is additive to natural mortality, so density-dependence was not incorporated into these conversions. The stochastic simulation model did make some simplifying assumptions, such as assigning age of first breeding to the second year of life for all but the seabirds, which would overestimate the number of potential breeders when breeding begins later, and by using nest success estimates that assume that nests were destroyed at the beginning of nesting, which would underestimate the number of potential breeders if nest destruction occurred later in the season. An important potential bias of the modeling process was the use of representative vital rates from only a few species, except the landbirds. In the future, more detailed estimates of species-specific kills could be incorporated with models using their species-specific vital rates to properly assess the effects of any particular mortality source. Finally, there are some considerations that the conversion to potential adult breeders could not incorporate. Long-lived, low-fecundity species take longer to recover from population perturbations, and mortality for these species is more likely to be additive than for shorter lived high-fecundity species. Additionally, long-lived, low-fecundity species tend to have much smaller population sizes, so a greater portion of the population is removed with each potential adult killed.

The risk mapping also relied on some important assumptions, specifically that mortality from each source was spread across the landscape in proportion to its existing spatial intensity. This is certainly not the case; forestry companies do not harvest equally across their tenure area and not every communication tower or wind turbine kills the average number of birds. However, adopting this assumption was necessary to create a first order spatial representation of the distribution of avian mortality risk across Canada.

The values considered here represent the current best estimates of source-specific annual bird mortality for Canada across all species groups and age classes, although a few sectoral mortality estimates must be considered to be quite preliminary, and there is some inherent uncertainty in all estimates. Moreover, because the magnitude of the estimates is likely to be fairly accurate, with true mortality levels contained within the estimation range, the relative ranking of mortality sources is unlikely to change substantially with improved precision.

CONCLUSIONS AND IMPLICATIONS

From a conservation perspective, it is now important to develop a more complete understanding of the population level effects of human-related avian mortality within and across sectors, at relevant spatial scales. Sources such as window strikes at houses cause high levels of mortality nation-wide, but this mortality is not spread equally across different species or families. Longcore et al. (2013) found similarly variable population impacts of communication tower collisions. Marine fisheries bycatch was not among the highest-ranking sources of mortality nation-wide, yet it kills disproportionately high numbers of birds from particular regional populations. Our assessment did not consider the fact that certain populations or species may still manifest a population-level consequence through additive effects of several mortality sources, even though each source individually would not be expected to show such an effect. Understanding these cumulative effects will not be possible until species-specific kill rates are available for all sectors. In the interim, those habitats or areas of the country where many sectors operate together are places where these multiple stressors have the potential to combine and create such a cumulative impact.

This synthesis and accompanying papers focus primarily on direct mortality of birds and destruction of nests resulting from human activities, but do not consider the potential longer term effects on birds from habitat changes. Wind turbines, for example, cause mortality by nest-destruction during construction as well as through collision mortality during operation. Indeed, recent evidence suggests that initial construction may sometimes pose a greater overall threat to birds (Pearce-Higgins et al. 2012). Commercial forestry, terrestrial oil and gas, and mining are further examples of activities where there may be significant longer term or broader scale effects of habitat modification that are not addressed here. Furthermore, mortality rates may change in the future for industries undergoing rapid rates of development, such as wind facilities, which are predicted to expand ten-fold in Canada over the next 10-15 years (CanWEA 2013). Human activities currently contributing relatively little to total mortality may therefore present a greater risk in years to come.

The complex relationships among all ecological factors regulating avian populations, and particularly migratory birds, require consideration of factors operating at points throughout the entire life cycle (Faaborg et al. 2010). For example, if wintering habitat conditions are not limiting, human-related mortality may be additive. However, if wintering habitat becomes limiting, human-related mortality may shift to being compensatory and its influence on population regulation may change. Improved understanding of species composition of mortality events, the magnitude of mortality of migrants south of Canada, and survival estimates at each life stage will be required to effectively model the demography of affected populations, particularly if bird conservation objectives include maintaining source-specific mortality from human-related causes below certain levels (e.g., McGowan and Ryan 2009, Runge et al. 2009, Dillingham and Fletcher 2011).

Insight into the relative magnitude of different human-related sources of mortality provides a valuable tool for guiding management, and affords additional perspectives for prioritizing conservation and research initiatives for Canada’s birds. We propose four key areas for future research or management. First, to enable more precise analyses and impact modeling, we recommend additional Canadian research into the magnitude of bird effects for data-poor sectors, e.g., pesticides, and the species likely affected, and into particular aspects of mortality, e.g., species composition and seasonal timing of the kill. Second, our results highlight the value of increased efforts to minimize impacts of widespread and generalized low-intensity human-related activities that create nationally high levels of mortality but could be mitigated at local scales, e.g., cats and buildings. Such investments could include local approaches using outreach and other available conservation tools. Third, we recommend specifically targeting those mortality sources identified as having population-level effects at regional or national levels for priority conservation action. Finally, we encourage further assessments that integrate the effects on populations across multiple sectors to truly understand the impacts of all mortality sources on priority species. Such mitigation efforts can reduce human-related impacts on birds if appropriately directed (as shown by e.g., Nocera et al. 2005, 2007: changing the timing of agricultural activities to reduce impacts on grassland breeders; Gehring et al. 2009: changing lights on communication towers to reduce collision mortality; and Løkkeborg 2011: modifying fishing gear to reduce bycatch of seabirds.

Given that the relative ranking of mortality sources considered here is unlikely to change substantially even with increased precision, an immediate focus should consider mitigation of those mortality sources with the highest magnitudes at the national level, e.g., cats and collisions. At the same time, scientists should try to identify and better understand potential population-level impacts on populations or species, at appropriate geographical scales. Effective application of these findings to the conservation of Canadian birds will require constructive collaboration among the public and various levels of government, nongovernmental organizations, and industries within Canada. This assessment should help target these initiatives appropriately to improve the population and conservation status of birds within Canada, as well as the continental conservation status for migratory species.

Acknowledgments:

This research was instigated and funded by Environment Canada. Thank you to Amos Chow for assistance in compiling some of the mapping data, to Beau MacDonald for providing quality-controlled communication tower data, to Alyssa Serena for compiling provincial game-bird harvest numbers, to Steve Van Wilgenburg and Keith Hobson for providing their landbird demographic rates, and to Peter Blancher for unpublished family-level abundance estimates. Finally, we thank the authors of all the papers and reports cited here on individual sources of human-related avian mortality for their feedback and clarification of their mortality estimates.

1 EXECUTIVE SUMMARY

ArborVitae Environmental Services Ltd. and ESSA Technologies Ltd. generated preliminary estimates of the magnitude of avian incidental take due to roadside maintenance operations across Canada. Eighteen roadside nesting species, all protected under the Migratory Birds Convention Act, were identified through the literature and expert advice. To model the impacts on these species, this study took a focal-species approach, in which estimates of incidental take were modeled for 6 focal species and then extrapolated to 12 other species which had similar ecologies. The estimates of take for the focal species were based on:

- their nesting ecology (i.e. nesting dates, number of eggs laid, incubation periods) and range in Canada;
- preferred nesting habitats relative to the availability of the habitats along roadsides; and
- the amount of road and maintenance activities conducted in each province.

We used a modeling approach which integrated the information above with assumed and calculated distributions of nesting period, road maintenance schedules, egg laying, etc.

Estimates of take were made for these species using a combination of modeling and extrapolation. Incidental take ranged from 7 (Lark Sparrow) to 820,000 (American Robin) individuals per year across Canada. We estimate that approximately 861,000 nestlings, eggs, and adults (only waterfowl adults are susceptible to incidental take) are killed by incidental take per year. However, this analysis, although very detailed, is subject to a number of caveats which suggest that the results should be interpreted with considerable caution.

There are no published criteria for what constitutes biologically significant levels of incidental take for bird populations. However, a widely accepted criterion for identifying key habitat sites for population conservation may serve as a suitable surrogate. Sites believed to support at least 1% of a Canadian population are considered to be key habitat sites, and their loss would potentially have a significant detrimental impact on the total population. By extension, losses to incidental take of 1% or more of a species Canadian population could be considered biologically significant (C. Machtans, pers. com.).

As a proportion of total Canadian populations, take was estimated to be less than 1% for all species, ranging from 0.0057% (Clay-colored Sparrow) to 0.5880% (American Robin). According to the 1% criterion, incidental take due to roadside maintenance operations is not a biologically significant mortality factor in Canada.

2 INTRODUCTION

The inadvertent destruction of birds and/or their nests and young occurs in Canada during otherwise legitimate operations in a variety of sectors, including forestry, mining, agriculture, electrical generation and transmission, fishing, structures, roadside maintenance and road construction. Such "incidental take" is an important factor in bird conservation and management, and Environment Canada has identified a need to better understand the magnitude and significance of the issue.

The objective of this project was to generate defensible species specific estimates of the number of birds killed annually due to roadside maintenance activities in Canada, by province/territory, e.g., for every hectare of roadside affected by mowing and/or brushing, an average of X number of individuals of species Y are killed each year. Only bird species that breed in Canada and are covered under the *Migratory Birds Convention Act* (MBCA) were included; species not protected by the MBCA include raptors, corvids, blackbirds, gallinaceous birds, and some others not explicitly mentioned in the *Act*. The temporal scope of the project was the breeding season, so winter maintenance activities such as snow management were excluded. Roadside maintenance activities in Canada include mowing, brushing (shrub cutting), and tree trimming. Some jurisdictions also use herbicides (e.g., Newfoundland/Labrador) to control vegetation, but this type of impact falls under the category of substances harmful to birds (as regulated by S5.1 of the MBCA), and was beyond the scope of the project. All roads for which roadside vegetation is managed by mechanical means were included in the analysis. Long-term resource roads that provide access to the back country were included, but short-term resource roads were out of scope.

This report documents a research and modeling effort to estimate the magnitude of avian mortality due to roadside maintenance activities, such as mowing and shrub brushing, across Canada. Roadside vegetation is managed for a variety of reasons, including safety (Forman et al. 2003; Jacobson 2005), aesthetics (Jacobson 2005), the control of invasive plant species, and in preparation for snow removal. Mowing-related avian mortality in roadside habitats is understood by many researchers to occur (e.g., Forman et al. 2003; Maguire 2007), but few studies have attempted to quantify it, and none have attempted to quantify it on a national scale. Even comprehensive reviews on the short- and long-term ecological effects of roads do not cover mortality from mowing equipment (Spellerberg 1998; Trombulak and Frissell 2000; Forman et al. 2003). In agricultural areas, bird use of strip-cover habitats such as road rights-of-way, fencerows, farmstead shelterbelts and grassed waterways can be high (Best et al. 1995). Such habitats provide nest sites, particularly shrubs and trees that are usually not available in the surrounding landscape. For bird species associated with roadside habitats, incidental take by mowing and other right-of-way maintenance operations may be a significant source of mortality.

A thorough literature review, combined with information from experts in the growing field of road ecology (see Appendix A), showed that data related to avian mortality due to roadside maintenance activities are virtually nonexistent. In North Dakota, Cook and Daggett (1995) reported "major losses" of birds to road right-of-way mowing; this loss includes ducks (34% of roadside duck nests have not hatched by the time the mowing occurs) and fledgling birds that could not escape the mowers. The same study estimated that 4,500 ducks are killed annually in the Prairie Pothole Region of North Dakota, but it isn't clear if this mortality is mowing-related or due to vehicle strikes. In a study in Iowa, roadside mowing destroyed only 2 of 98 nests in 34 roadside plots that covered 10.2 hectares (Camp and Best 1994); predation was the major mortality factor. In Illinois, 13 of 91 ring-necked pheasant roadside nests were destroyed by mowing (Joselyn et al. 1968). A California study reported the inadvertent destruction of 4 burrowing owl nests on an 800 m stretch of road due to roadside maintenance activities; 3 adult owls were also killed (Catlin and Rosenberg 2006). In a Danish study, roadside mowing was confirmed responsible for the loss of 1 of 3 skylark nests over a 4.7 km stretch of roadway (Laursen 1981). In Oregon, two maintenance workers estimated they killed between 400 and 600 birds during early July mowing operations (Braun et al. 1978, in Dale 1993). Jackson and Jackson (2000) characterized some gravel roadsides as ecological sinks for killdeer due to the negative impacts of pesticides and "destruction of eggs and chicks"; it isn't clear, however, if this destruction was due to roadside maintenance or to some other form of road-related activity. In other published studies, mortality due to roadside mowing is implied by results that show lower productivity following mowing (Dale et al. 1997), higher nesting success where mowing was delayed (e.g., Oetting and Cassel 1971; Dale 1993; Leif 2004), or higher nest densities in unmowed vs. mowed roadside (Berner 1984:32 *in* MDNR 2005). In many instances, maintenance-related mortality is understood to occur, but no empirical evidence is provided (e.g., Farris et al. 1977; Camp and Best 1994; Jacobson 2005; Belanger et al. 2006; Maguire 2007).

3 METHODS

Given the nearly total absence of empirical data about bird mortality as a result of roadside maintenance operations, we chose a modelling approach to estimate incidental take (Appendix B). To do this, we needed to: 1) derive a list of bird species likely to nest in roadside habitats; 2) gather breeding and nest density information for those species; and 3) obtain information about the area disturbed by maintenance activities in each province and territory.

3.1 Deriving a List of Roadside nesting Birds

A search of the literature established that no recognized "roadside nesting guild" of birds exists in published works, including Forman et al. (2003). We used a combination of expert opinion and literature to build a list of species likely to nest in road rights-of-way across Canada. As noted earlier, only species covered by the MBCA were considered for inclusion, which explains the otherwise noteworthy absence from the list of species like red-winged blackbird and ring-necked pheasant. The species on the list were then grouped according to general habitat requirements based on the literature listed in Table 1. For each group, a single focal species was selected to represent the group's risk of exposure to mortality from mowing and brushing operations. This approach was adapted from the approach taken by Tews et al. (2009) for the incidental take analysis of the agriculture sector.

The list of roadside nesting birds (Table 1), with habitat groupings and focal species, was then reviewed by grassland bird experts from Environment Canada (K. Lindsay, B.Dale) and revised accordingly.

Table 1: List of roadside nesting bird species, organized into groups according to general habitat characteristics. Focal species for each group are indicted in bold text.

General Habitat Characteristics	Nest Elevation	Species	Source
bare ground or sparse, low vegetation	ground	**Killdeer**	Oetting and Cassel 1971; Peck and James 1983; Best et al. 1995
denser, taller vegetation	elevated	American Goldfinch	Peck and James 1987; McGraw and Middleton 2009
denser, taller vegetation	ground	Eastern Meadowlark	Hergenrader 1962; Peck and James 1987; Warner 1992; Best et al. 1995; Leif 2004; MDNR 2005; Shochat et al. 2005
denser, taller vegetation	ground	**Savannah Sparrow**	Peck and James 1987; Best et al. 1995; MDNR 2005; Wheelwright and Rising 2008; Brenda Dale, pers. com.
denser, taller vegetation	ground	Western Meadowlark	Hergenrader 1962; Warner 1992; Camp and Best 1994; Best et al. 1995; Leif 2004; MDNR 2005

grassy fields; meadows	ground	Northern Pintail	Peck and James 1983
grassy fields; meadows	ground	Northern Shoveler	Peck and James 1983

3.2 GATHERING BREEDING AND NEST DENSITY INFORMATION

In order to model the number of individual birds (adults, eggs and nestlings) that are killed annually by roadside mowing and brushing operations, we needed to assemble breeding and nest density information for each of the focal species on the bird list (Table 2).

Table 2: Model parameter input information for birds.

Parameter	Description
egg dates	the earliest and latest dates on which viable eggs have been recorded in nests (Peck and James 1987:2)
incubation time	average # days from date of last egg laid to hatch
nestling time	average # days in nest after hatching
temporal distribution of egg-laying	use start date regression model to determine proportion of nests initiated by date (as per Tews et al. 2009)
temporal distribution of fledging	assumed to be the same as distribution of egg-laying, i.e., fixed number of days for incubation and nestling time
clutch size	average number of eggs per nest
nest densities	average # nests per hectare, in each of 4 general habitat types

The assumptions inherent in the parameter definitions in Table 2 are:

- 1 brood per pair and no re-nesting (as per Tews et al. 2009); most of the focal species on the list of roadside birds are known or suspected to be capable of raising second broods (killdeer, savannah sparrow, song sparrow, vesper sparrow) (Peck and James 1987), but further research is needed to gather the information necessary to incorporate this factor into the calculations of take
- 100% of eggs laid are fertile and represent a bird for the purposes of incidental take
- hatching success is 100%, i.e., the number of fledglings equals the number of eggs
- the nestlings of altricial species stay in or near the nest until fledged, and are therefore vulnerable to mowing/brushing equipment for the entire nestling period; the nestlings of killdeer (the only precocial species on the list) are led away from the nest by their parents within 2 days of hatching (Davis 1943 *in* Ankney 1985), travelling long distances (greater than 100 m) to brood rearing habitats (Powell 1993), at which time they are no longer vulnerable to mowing/brushing equipment

Natural mortality was not deducted from our estimates (pers. comm. C. Machtans and B. Dale, Environment Canada). The consensus was that a nestling killed by a mower constitutes incidental take no matter if that nestling would have later died of other anthropogenic or non-anthropogenic causes. These assumptions will therefore generate a maximum estimate of incidental take.

To maximize efficiency, we used the breeding information compiled by Tews et al. (2009)[1] whenever possible, i.e., for focal species that were common to both projects. For other focal species, we used Peck and James (1983, 1987) and the Birds of North America online as resources.

To determine estimates for nest densities by habitat type, we used the Canadian Breeding Bird Census (CBBC) database (see Kennedy et al. 1999) which reports adult densities (birds/km^2) derived from "spot- or territory-mapping" censuses from 640 sites spread across 76 of Canada's 194 ecoregions (Figure 1) (Blancher 2002).

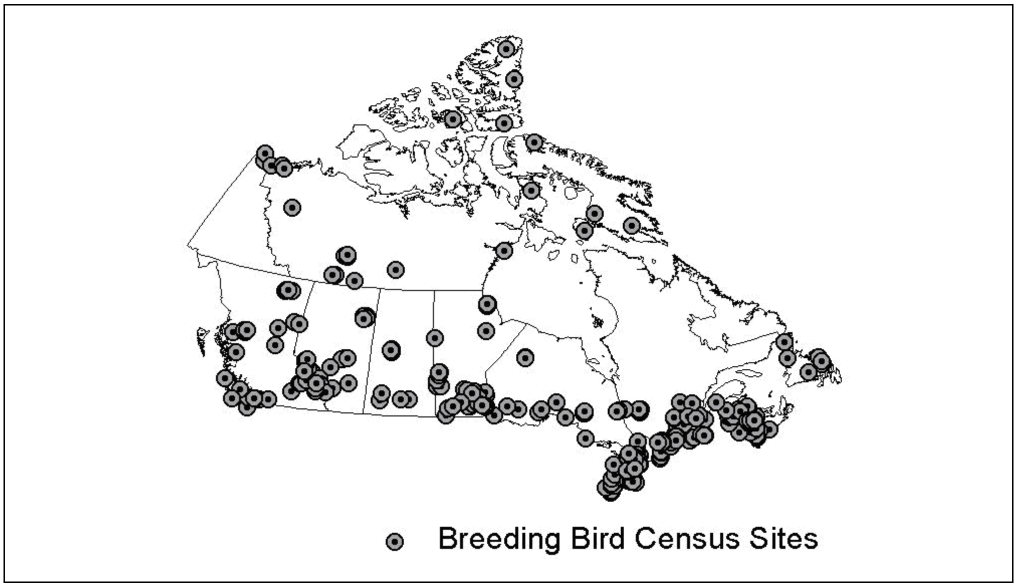

Figure 1. Canadian Breeding Bird Census sites (from Blancher 2002).

For each of our focal species, we mapped the habitats in the CBBC to 4 general habitat types – Forest, Shrubland, Grassland And Wetland. For example, "grazed pasture" and "clover-alfalfa-timothy field" both mapped to Grassland, whereas "old field with hedgerows" and "tall bottomland willow stand" both mapped to Shrubland. This both simplified and standardized the relevant habitats, and made them compatible with the Land Cover classes available to us for the GIS analysis (see Table 5, below). For provinces/territories within a species range that had no density estimates in the CBBC, we used densities from the nearest neighbouring province/territory for which there were data. Where multiple values were available, we used the mean value. The strength of the CBBC is that it provides habitat-specific density estimates by species and by province/territory; its weaknesses are: 1) older data; 2) low sample sizes, precluding fine resolution analysis; and 3) non-random sampling sites, which make it unclear to what extent densities are representative of areas not sampled (Blancher 2002). Additionally,

---

[1] We are indebted to Pierre Mineau, Environment Canada (Ottawa) for access to these data.

the CBBC under-represents the boreal and taiga regions of Canada (see Figure 1, above), and there are no census data for the province of Prince Edward Island.

The bird breeding and density inputs used in the simulation model are shown in Appendix C. Further research and analysis could be done to refine these density estimates (e.g., using the approach taken by Blancher (2002)), including incorporation of data from the Northwest Territories / Nunavut Bird Checklist Survey, and data for Prince Edward Island. Density values can easily be updated in the model if/when better information becomes available.

Accounting for Habitat Quality

Bird species that occur in roadside habitats tend to be similar to those of the adjacent habitat (Meunier et al. 1999; Belanger et al. 2006). However, road rights-of-way are probably not preferred habitat for any of the species that nest there, except possibly killdeer (Jackson and Jackson 2000). In a study in southern Quebec, species richness and bird abundance were both greater in the adjacent habitats than in the road rights-of-way (Belanger et al. 2006). Given that roadside nesting species tend to be open country birds, roads that run through closed forest habitat probably have fewer breeding birds using the roadside than those running through open habitat. Exceptions to this general rule are probably habitat generalists (e.g., song sparrow) and species that use woodland edges such as Mourning Dove and Indigo Bunting. In an attempt to address this issue, we decided to incorporate habitat quality into the analysis. For each focal species, we categorized roadside habitat as either moderate or poor quality, based on the surrounding habitat type and the habitat preferences of each species. Sources for species habitat information were Peck and James (1983, 1987), Birds of North America online, and the CBBC database (Kennedy et al. 1999). Each category was then assigned a multiplier so we could discount nest density values to account for the habitat quality factor. The multipliers we used were 0.5 for moderate quality habitat and 0.1 for poor quality habitat. For example, if the density of savannah sparrow nests in preferred habitat was 1 per hectare, then our analysis would use half of that density for roads running through open country and one tenth of that density for roads running through forests. These multiplier values should be considered placeholders; an attempt to validate/revise them with research and expert opinion still needs to be made.

Additionally, we have allowed for some variation in roadside habitat type in our analysis. For example, a road running through open country might have a right-of-way composed mostly of grasses and herbs, whereas a road running through a forest may tend to have more of a woody component.

The combinations of habitat type and quality used for each focal species are listed in Table 3.

Table 3. Combinations of habitat type and quality for each focal species. Surrounding Habitat is the habitat through which the roadside runs, and Right-of-Way Habitat is the habitat assumed to be available to nesting birds along the roadside. Habitat Quality Multipliers are used in the analysis to discount nest densities in non-preferred habitats.

Killdeer

Surrounding Habitat	Right-of-Way Habitat (Habitat Quality)	Habitat Quality Multipliers
Forest	50% grass (poor), 50% shrub (poor)	0.1, 0.1
Grassland	100% grass (moderate)	no discount
Shrubland	50% grass (moderate), 50% shrub (moderate)	no discount
Wetland	50% grass (moderate), 50% wetland (moderate)	no discount

Savannah Sparrow

Surrounding Habitat	Habitat of Road Right-of-Way (Habitat Quality)	Habitat Quality Multipliers
Forest	50% grass (poor), 50% shrub (poor)	0.1, 0.1
Grassland	100% grass (moderate)	0.5
Shrubland	50% grass (moderate), 50% shrub (poor)	0.5, 0.1
Wetland	50% grass (moderate), 50% wetland (poor)	0.5, 0.1

Song Sparrow

Surrounding Habitat	Habitat of Road Right-of-Way (Habitat Quality)	Habitat Quality Multipliers
Forest	50% grass (moderate), 50% shrub (moderate)	0.5, 0.5
Grassland	100% grass (poor)	0.1
Shrubland	50% grass (moderate), 50% shrub (moderate)	0.5, 0.5
Wetland	50% grass (poor), 50% wetland (poor)	0.1, 0.1

Clay-Colored Sparrow

Surrounding Habitat	Habitat of Road Right-of-Way (Habitat Quality)	Habitat Quality Multipliers
Forest	50% grass (poor), 50% shrub (poor)	0.1, 0.1
Grassland	100% grass (poor)	0.1
Shrubland	50% grass (moderate), 50% shrub (moderate)	0.5, 0.5
Wetland	50% grass (poor), 50% wetland (poor)	0.1, 0.1

Vesper Sparrow

Surrounding Habitat	Habitat of Road Right-of-Way (Habitat Quality)	Habitat Quality Multipliers
Forest	50% grass (poor), 50% shrub (poor)	0.1, 0.1
Grassland	100% grass (moderate)	0.5
Shrubland	50% grass (moderate), 50% shrub (moderate)	0.5, 0.5
Wetland	50% grass (poor), 50% wetland (poor)	0.1, 0.1

Mallard

Surrounding Habitat	Habitat of Road Right-of-Way (Habitat Quality)	Habitat Quality Multipliers
Forest	50% grass (poor), 50% shrub (poor)	0.1, 0.1
Grassland	100% grass (moderate)	0.5
Shrubland	50% grass (moderate), 50% shrub (moderate)	0.5, 0.5
Wetland	50% grass (moderate), 50% wetland (moderate)	0.5, 0.5

3.3 OBTAINING INFORMATION ABOUT AREA DISTURBED

The task of estimating area disturbed by mowing and/or brushing required a number of inputs. These included:

- total number of kilometers of roads by province/territory
- total number of kilometers of roads within the breeding ranges of each focal species in each province/territory
- total number of kilometers of roads in each of 4 general land cover types (forest, grassland, shrubland, wetland) within the breeding range of each focal species – for determining how to apply the habitat quality multipliers to nest density values
- total number of hectares mowed and/or brushed in each province/territory
- timing information for the disturbance

GIS Analysis
A GIS analysis was needed to obtain the required information about the extent of roads in each province and habitat type, and within each focal species breeding range.

The first step in this process was identifying an efficient, electronic source for the extent of Canada's road network. This source was the National Road Network of Canada (NRNC), available free of charge via the GeoBase web portal. The NRNC is the responsibility of Natural Resources Canada, and contains current, accurate geospatial data about Canada's roads. The NRNC is maintained under a federal-provincial-territorial-municipal agreement, and updates occur at least once per year.

The NRNC GIS layer included some road classes that were unlikely to result in incidental take for various reasons, and these were excluded from the analysis. The excluded road classes were: 1) winter roads; 2) local streets and back alleyways; and 3) rapid transit lanes for buses. Winter roads were excluded because the winter season is out of scope for our estimate of take. For the other excluded classes, we felt that their rights-of-way would either be too regularly maintained to be viable habitat for nesting birds (e.g., weekly mowing of rights-of-way by private property owners as in a subdivision), or they would be sidewalks (e.g., urban areas). The road classes that we did include in the analysis are listed in Table 4 - these are the roads that we considered likely to be maintained by government resources.

Table 4. Road classes included in the GIS analysis for kilometers of road in each province/territory.

Code	Road Class	Description
1	Freeway	An unimpeded, high speed controlled access thoroughfare for through traffic with typically no at grade intersections, usually with no property access or direct access and which is accessed by a Ramp. Pedestrians prohibited.
2	Expressway / Highway	A high-speed thoroughfare with a combination of controlled access intersections at any grade.
3	Arterial	A major thoroughfare with medium to large traffic capacity.
4	Collector	A minor thoroughfare mainly used to access properties and to feed traffic with right of way.
9	Ramp	A system of interconnecting roadways providing for the controlled movement between two or more roadways.
10	Resource / Recreation	A narrow passage whose primary function is to provide access for resource extraction and may also serve in providing public access to the backcountry.
12	Service Lane	A stretch of road permitting vehicles to come to a stop along a Freeway or Highway. Scale, service lane, emergency lane, lookout and rest area.

Habitat types for all of Canada were also available from the GeoBase web portal, in the form of 250 separate land cover shapefiles. This land cover information comes from Landsat 5 and Landsat 7 ortho-images produced by the Canadian Forest Service (CFS) for the forested areas, by Agriculture and Agri-Food Canada (AAFC) for the agricultural areas, and by the Canadian Centre of Remote Sensing (CCRS) for the northern territories. The land cover classification system used is a harmonization of existing systems used by these three agencies, and is summarized at http://www.geobase.ca/doc/specs/pdf/GeoBase_LCC2000V_Harmonization_Legend.pdf. The harmonized classification contains 43 land cover types, 10 of which are un-vegetated. From these, we created 4 general habitat types – Forest, Shrubland, Grassland and Wetland – that captured 91% of vegetated land cover classes in Canada (Table 5).

Table 5. General habitat types used in the analysis and the land cover classes that comprise them; these 4 Habitat Types represent 91% of the vegetated land covers classes in Canada.

Habitat Types	Land Cover Classes	Legend Code
Grassland	Herb	100
	Tussock graminoid tundra	101
	Grassland	110
	Cultivated Agricultural Land	121
	Annual Crops	122
	Perennial Crops and Pastures	123
Shrubland	Shrubland	50
	Shrub- Tall	51
	Shrub – Low	52
	Prostrate dwarf shrub	53
	Moist to dry non-tussock graminoid/shrub tundra	103
	Dry graminoid prostrate dwarf shrub	104
Forest	Forest/Trees	200
	Coniferous	210
	Coniferous– Dense	211
	Coniferous – Open	212

Habitat Types	Land Cover Classes	Legend Code
	Coniferous – Sparse	213
	Broadleaf	220
	Broadleaf – Dense	221
	Broadleaf – Open	222
	Broadleaf – Sparse	223
	Mixedwood	230
	Mixedwood – Dense	231
	Mixedwood – Open	232
	Mixedwood – Sparse	233
Wetland	Wetland	80
	Wetland Treed	81
	Wetland Shrub	82
	Wetland Herb	83
	Wet Sedge	102

The final input for the GIS analysis was information about the breeding ranges of each focal species on the list from NatureServe 3.0 (http://www.natureserve.org/getData/birdMaps.jsp).

The total number of kilometers of maintained road (filtered as described above) in each province/territory is shown in Table 6.

Table 6. The extent of roads in Canada, by province and territory.

Province/Territory	Total Maintenance[1] Road Length (km)	Total Road Length (km)
BC	32,669	77,248
Yukon	3,660	6,043
NW Territories	2,773	5,358
Alberta	221,211	231,567
Saskatchewan	239,662	250,455
Manitoba	78,610	87,864
Ontario	99,591	234,769
Quebec	113,965	146,586
New Brunswick	26,731	31,740
Nova Scotia	21,741	45,707
PEI	3,500	6,708
Newfoundland/Labrador	16,143	19,632
Nunavut	405	916
Total	860,661	1,144,596

[1] Maintenance road length reflects the exclusion of urban and suburban roads.

The unfiltered total extent of roads in Canada, based on the NRNC data, is approximately 1.1 M km. This agrees reasonably well with Forman et al. (2003:38), who reported a total of 902,000 km of 2-lane equivalent roadway in Canada for the year 2000. Of these, 574,000 km are unpaved, 312,000 km are paved, and 16,000 km are freeways. The process of filtering out the surburban/urban and rapid transit road classes has reduced total road extent for each province and territory; in some cases, the reduction is quite substantial (e.g. road length in Ontario was reduced from 235,000 to 99,000 km). This may not be an unreasonable result, given the extensive road networks in the many cities and towns of southern Ontario. Additionally, our filtering resulted in a total maintenance road length for British Columbia that was surprisingly small (<33,000 km). However, contacts at the British Columbia Ministry of Transportation, verified this value as reasonable since they maintain about 47,000 km of roads including some suburban/urban.

The number of kilometers of maintenance road (filtered as described above) within each focal species breeding range is shown in Table 7.

Table 7. Number of kilometers of road (filtered) within the breeding range for 6 focal species.

Researching Area Disturbed

Information about area disturbed was collected from provincial and territorial transportation ministries (contacts are provided in Appendix A); these agencies managed most of the road kilometers in the country. Some jurisdictions did not provide data, so it was necessary to generate estimates for them based on information obtained from the responding jurisdictions. For each province/territory that provided disturbance data, we calculated the proportion of total roadside hectares that were mowed or brushed. We then averaged the proportion maintained for the responding provinces/territories, and applied this proportion to the total roadside hectares for all non-respondent jurisdictions to derive an estimate of area maintained for them. In terms of the timing of maintenance operations for non-respondent jurisdictions, we assumed an even distribution of effort between June and August inclusive, unless information obtained from interviews with transportation contacts indicated otherwise.

The road maintenance inputs used in the simulation model are shown in Appendix C. These values can easily be updated in the model if/when better quality data become available.

3.4 CALCULATING INCIDENTAL TAKE

Disturbance data were expressed as total area by province/territory (analysis region). Area disturbed within each region for each focal species was derived by overlaying the digital road data with the digital bird distribution data. This approach assumes an even distribution of area disturbed across all roads within each province/territory.

The mortality rate for eggs and nestlings exposed to maintenance operations was assumed to be 100% for all focal species; adult mortality was assumed to be 0% for all focal species except waterfowl (after Tews et al. 2009). A literature review provided in Tews et al. (2009) noted that some proportion of nesting adults of most waterfowl species are subject to mortality from mowing. We have used a mortality rate of 23.5% (i.e. 23.5 adults killed per 100 nests destroyed), consistent with Tews.

For each focal species (except mallard), the total number of birds killed by maintenance operations was calculated by multiplying the number of eggs/nestlings present on a given day (after adjustments for habitat quality) by the number of hectares disturbed on the same day and then summing these results across all days within the breeding range and within each province/territory. For mallards, the number of adults killed, based on nest density, was tallied separately from the number of eggs/nestlings affected.

For each focal species, we calculated the proportion of birds killed relative to published estimates of total population size for each province/territory. Population estimates were obtained from the Partners in Flight/Breeding Bird Survey online database (http://rmbo.org/pif_db/laped) (see Blancher et al. 2007) for the landbirds (savannah sparrow, song sparrow, clay-colored sparrow and vesper sparrow) and from Blancher (2002) for killdeer. For Mallards, population estimates were obtained for the Prairie Provinces from provincial North American Waterfowl Management Plan (NAWMP) implementation plans prepared under the Prairie Habitat Joint Venture (PHJV) (Manitoba Implementation Plan Committee 2008, Saskatchewan NAWMP Technical Committee 2008, Alberta NAWMP Partnership Management Committee 2008). Data used were the 2007 10-year average breeding population for the area covered by the PHJV for each province. Comparable data were not available for other provinces. For Ontario, Quebec and the Maritime provinces, data were provided by the Canadian Wildlife Service (J. Hughes pers. comm.) based on stratified surveys from areal and ground reconnaissance last completed in 2005. Data for British Columbia and the territories could not be obtained. These proportions were used to calculate incidental take for all non-focal roadside species (as per Tews et al. 2009). For example, if an average of 0.1% of savannah sparrows in Ontario were calculated to be lost to roadside maintenance operations, we applied the same percent loss to the non-focal members of the group in that province. This approach assumes that take for non-focal species is proportionately similar to take for focal species.

4 RESULTS

We calculated that approximately 494,000 to 1.525 million birds are killed annually (median value approx. 861,000) by maintenance operations. Most (95%) of these are American robins (but see discussion in Section 5 explaining the calculated robin mortality). On a proportional basis, incidental take was less than 1% of the total population for all focal species[2] at the national scale.

For the 6 focal species, the estimated number of birds (adults, eggs and nestlings) lost each year in Canada as a result of roadside maintenance activities is presented for each province/territory in Table 8, and for all of Canada in Table 9. Of the focal species, the highest level of calculated take is for savannah sparrow (approx. 9,300), and the least for clay-coloured sparrow (approx. 1,090). No obvious trends are apparent, as levels of take are largely a function of the nest densities in the various provinces, affinity for roadside habitat, and nesting ecology (i.e. dates of egg-laying, incubation times, etc.) as described in Section 3.4 and in considerable detail in Appendix B.

Estimates extrapolated to the non-focal roadside nesting species are provided in Table 10. Totals are summarised in Table 11. For the non-focal species the highest level of estimate mortality is, for American robin, and the least for lark sparrow (median value 7).

Table 8. Incidental take for 6 focal species by province/territory. Mortality = number of birds (adults, nestlings, eggs) killed by maintenance operations. POP= population estimates- from Partners in Flight Landbird Database for all birds except mallards; for mallards population estimates were taken from the Habitat Joint Ventures as explained in text. %Pop = the percent of the population killed, and is used for calculation of incidental take of non-focal species in each group. The median (50%), and the 50th percentile and the 95% percentile interval from 1000 simulations are reported, where LB (lower bound) = 2.5 percentile and UB (upper bound) = 97.5 percentile. For all species except mallard, mortality is eggs and nestlings only; for mallards mortality of adults is indicated separately from mortality of eggs and nestlings.

Focal Species Total		**25,298**	**13,170**	**50,564**				

[1] Because killdeer is the only member of its group, there is no need to calculate a value for %Pop to use in calculating the incidental take of non-focal species in the same group.

[2] Population estimates from Partners in Flight combine Nunavut and the Northwest Territories, so estimates of incidental take for these two territories have been combined in order to calculate %Pop.

[3] Mallard population estimates were not available for BC, Nunavut, NWT and Yukon.

Table 9. Incident take for 6 focal species for all of Canada. Total Take = number of birds killed annually in Canada. %Tot = percent of the total annual take. Median, lower bound (LB=2.5 percentile) and upper bound (UB= 97.5 percentile) values are reported.

	Total Take (%Tot)		
	Median	LB	UB
Killdeer	2,026 (8.1)	1,275 (9.7)	3,216 (6.4)
Savannah Sparrow	9,306 (36.7)	4,349 (33.0)	20,640 (40.8)
Song Sparrow	4,175 (16.5)	2,096 (15.9)	8,470 (16.8)
Clay-colored Sparrow	1,088 (4.3)	462 (3.5)	2,757 (5.4)
Vesper Sparrow	3,053 (12.1)	1,805 (13.7)	5,197 (10.3)
Mallard (eggs/nestlings)	5,501(21.7)	3,099(23.5)	10,014(19.8)
Mallard (adults)	149(0.6)	84(0.6)	270(0.5)
Total	25,298 (100)	13,170 (100)	50,564 (100)

Table 10. Incidental take for 12 non-focal species by province/territory. %Pop focal = the percent of the focal species population killed (from Table 8). Pop Est - population estimates. Estimated take (Mortality) = Number of birds (adults, nestlings, eggs) killed by maintenance operations, calculated as proportion lost (%Pop focal/100) multiplied by the population size of the non-focal species. LB = lower bound on the estimate; UB = upper bound on the estimate. For example: for American Goldfinch in Alberta, we estimate (0.0162/100)*840,000=136.08 birds as the median take. Note that separate estimates are provided for waterfowl eggs and nestlings, and adults.

---

[1] Clay-colored Sparrow (CCSP) is the focal species for the group containing American Robin (AMRO). AMRO occurs in the maritime provinces, but CCSP does not. To calculate estimated take values for AMRO in the maritime provinces, we averaged CCSP % take over all provinces/territories in which it occurred, and used these values for AMRO %Pop focal.

2 Population estimates for all waterfowl (Including Mallards) were not available for BC, or any of the Territories. As no estimates of take were possible those jurisdictions are not included in this table.

3 Because no mallard data were available to calculate density information for Newfoundland and PEI (as the provinces are mostly out of the species' range), we used average results for NB, NS, and QC in this calculation of take for black duck

Table 11. Total annual estimated incidental take for 18 bird species affected by roadside maintenance operations across Canada. Species indicated in bold are focal species. Estimates are based on median totals in Table 8 and Table 10.

Common Name	Estimated Take	Total CDN Pop	% Total CDN Pop
Killdeer [1]	2,026	1,613,200	0.1256
Savannah Sparrow	9,306	35,770,000	0.0260
American Goldfinch	2,833	8,410,000	0.0337
Eastern Meadowlark	129	260,300	0.0496
Western Meadowlark	473	2,596,000	0.0182
Song Sparrow	4,175	24,030,000	0.0174
Mourning Dove	1,430	5,315,400	0.0269
Indigo Bunting	181	454,000	0.0399
Clay-colored Sparrow	1,088	18,982,000	0.0057
American Robin	819,612	139,400,000	0.5880
Vesper Sparrow	3,053	10,692,600	0.0286
Lark Sparrow	7	43,000	0.0173
American Black Duck[2,3]	4,935	673,400	0.7328
Blue-winged Teal[2,3]	1,563	1,172,700	0.1333
Gadwall[2,3]	1,182	1,165,000	0.1015
Mallard[2,3]	5,650	3,857,800	0.1465
Northern Pintail[2,3]	1,017	1,025,500	0.0992
Northern Shoveler[2,3]	2,367	1,757,500	0.1347

[1] The estimated total Canadian population size for killdeer is an average of 5 values from Blancher (2002), including one from Morrison et al. (2001).

[2] Data shown for waterfowl is the sum of eggs, nestlings and adults

[3] Data for waterfowl populations was incomplete, see discussion in text.

Table 12. Total annual estimated take (based on median values from Table 8 and Table 10) for 6 focal species and 12 non-focal species.

	Province/Territory

5 DISCUSSION

The biological significance of incidental take for bird populations is as yet unknown. Populations of many species are declining, but the role of take in these declines is anything but clear. The impact of take is likely to vary from species to species, and from region to region. Effects may occur locally but not regionally. For sectors in which incidental take kills individuals regardless of condition (e.g., window strikes at structures), the impact on populations may be greater than for factors that cause mortality among weaker individuals (e.g., predation by house cats). Additionally, incidental take that kills adults can be expected to have a greater impact at the population level than where mortality is predominantly juveniles.

For the roads sector, incidental take is an indiscriminant mortality factor, taking individuals regardless of their condition. On the other hand, take is mostly juvenile birds (eggs and nestlings) rather than adults. We estimated mortality of adult waterfowl, based on documented evidence that they are susceptible to take in agricultural mowing. Our calculations suggest than the total amount of adult take is less than 3% of that of the take of eggs and nestlings. As such, in general, this source of incidental take affects recruitment but does not greatly diminish the population of breeding adults. Even so, if recruitment gets reduced to the point where it becomes insufficient to maintain the population over the long term, then incidental take will have created a local population sink.

There are no published criteria for what constitutes biologically significant levels of incidental take for bird populations. However, a widely accepted criterion for identifying key habitat sites for population conservation may serve as a suitable surrogate. Key habitat sites are those that are so important that their loss could have a significant detrimental impact on the total population (Latour et al. 2006). Sites believed to support at least 1% of a Canadian population are considered to be key habitat sites. By extension, losses to incidental take of 1% or more of a species Canadian population could be considered biologically significant (C. Machtans, pers. com.).

At the national scale, our calculations suggest that take approaches 1% only for black ducks (0.73%). For all other species, levels of take are considerably less than 1% (Table 11). The seemingly high proportion of take for black ducks seems to be a function of their high population in Quebec, for which incidental take of mallards (the focal species) was estimated to be high. According to the 1% criterion, incidental take due to roadside maintenance operations is not a biologically significant mortality factor in Canada. In fact, given that most take was for nestlings and eggs, which generally have low survival rates, the impact of this source of take likely very small.

At the provincial scale, clay-colored sparrow was the only focal species that experienced take of 1% or more of its population. Modelling results showed an estimated 2.0 - 5.9% (median 3.5%) of the Quebec population clay-colored sparrows is killed each year by roadside maintenance operations. Two factors contributed to this result. Quebec represents the easternmost limit of clay-colored sparrow breeding range, and the provincial population is small relative to populations in all other provinces and territories in which it occurs. The number of birds lost to incidental take will have a larger proportional impact on small populations than on larger ones, resulting in a relatively high value for Quebec. Additionally, the species range in Quebec covers the road-rich southwestern corner of the province, where over 13,000 km of road intersect with clay-colored sparrow breeding range (see Table 7). If the 1% criterion can also be applied at the provincial scale, then it is likely that maintenance-related incidental take has a biologically significant impact on the clay-colored sparrow population in Quebec. No other focal species experienced take of 1% or more of their provincial population.

Among the non-focal species, the American robin in Quebec experiences the highest total incidental take due to roadside maintenance. Our model estimated that 820,000 eggs and nestlings are destroyed annually in Quebec as a result of roadside maintenance operations. This result is largely an artifact of the way take has been calculated. The focal species for American robin was clay-colored sparrow which experienced particularly high proportional take in Quebec. Applying this high proportional take to the population estimate for robins in Quebec (20,000,000 birds) results in a very large number of birds lost to incidental take. Consequently, Quebec accounts for the bulk (84.6%) of all incidental take of American robins in Canada, and American robin take comprises 95% of the total take for Canada. Even so, this level of take represents only 0.588% of the Canadian population of American robin (139,400,000 birds), so does not exceed the 1% criterion for biological significance.

Maintained road rights-of-way are open habitats. Many of the birds that nest along roadsides are grassland birds. As a group, grassland birds have experienced population declines over the past three decades that far exceed those of any other group of North American birds; loss of grassland habitat on breeding grounds is the most likely cause (Herkert et al. 2003). In areas of intensive agriculture, roadsides may represent an attractive alternative habitat for many open country bird species (Oetting and Cassel 1971; Voorhees and Cassel 1980; Dale 1993; Belanger et al. 2006). On the other hand, the benefits to productivity of this alternative habitat are counter-balanced at least somewhat by the risks associated with it. Not only is there a demonstrable risk of mortality from maintenance operations in roadside habitats, there is also higher mortality from predation in these habitats (Haensly et al. 1987; Camp and Best 1994). Road rights-of-way are linear, and can serve as travel corridors for mammalian predators (Dale 1993). Additionally, productivity can be adversely affected by avian predators, particularly if the right-of-way contains a fenceline (Evans and Wolfe 1967; Meunier et al. 2000). Brood parasitism by the brown-headed cowbird can also be a factor that affects productivity in habitats with a lot of edge, such as a roadside (Herkert et al. 2003).

Despite the risks associated with roadside nesting, there is still tremendous potential for managing roadside habitats to offset productivity losses among grassland and other open country bird species in Canada. Where roadside mowing can be avoided, or delayed until after young-of-the-year have fledged, nesting success will improve (Oetting and Cassel 1971; Berner 1984:32 *in* MDNR 2005; Dale 1993; Cook and Daggett 1995; Leif 2004).

Mitigating Incidental Take

Some provinces have environmental policies in place that prohibit the incidental take of birds (nests, eggs, nestlings) during road maintenance and construction operations. In British Columbia, maintenance specifications state that the contractors must comply with the Province's Environmental Best Practices for Highway Maintenance Activities (BCMTI 2009a: Section 5.10). These standards state that operations must cause "No injury, molestation or destruction of a bird, its eggs, and occupied nest, or the nest of an eagle, Peregrine Falcon, Gyrfalcon, Osprey, heron, or Burrowing Owl, unless the species is listed under Schedule C as exempt from this protection (*Wildlife Act*, Section 34)". Permits must be obtained for any activity that will affect migratory birds. Construction work must comply with federal (including the MBCA), provincial, municipal and local laws to ensure that work does not adversely affect the environment (BCMTI 2009b, Section 165). If clearing must occur during the breeding season for birds, the area is surveyed for active nests before work begins. If active nests are found, clearing is either delayed or a 30 m "no clear" buffer is established to mitigate disturbance

(Angela Buckingham, pers. com.). These requirements are expressly stated in construction contracts.

In Ontario, specific environmental protection requirements are imposed on road maintenance and construction operations by the Ministry of Transportation Ontario (MTO), including the protection of active bird nests (MTO 2006a:11; MTO 2006b:12). Construction contracts contain "Bird Nesting Preventative Measures" requirements (NSP 9051) that state "No work is permitted to proceed that would result in the destruction of active nests (nests with eggs or young birds), or the wounding or killing of birds, of species protected under the *Migratory Birds Convention Act*, 1994 and/or Regulations under that Act". Maintenance operations must comply with Maintenance Special Provision SSP 080S06, which requires operators to conduct a visual inspection for bird nests in all areas of work. If active nests are found, operators must either protect the nest or suspend operations. MTO takes the migratory bird issue "very seriously", and the agency is continually looking for better ways to minimize interference with active nesting (John Small, pers. com.). Because these mitigations are not strictly timing mitigations, i.e., operations occur during the breeding season, our modeling results will probably overestimate incidental take for Ontario's provincially-managed roads by reporting take that may not actually occur.

The Province of Saskatchewan requires that road construction operations comply "with all federal, provincial, municipal and local laws and regulations which seek to ensure that construction work does not adversely affect the environment", including the *Migratory Bird Convention Act* (see http://www.highways.gov.sk.ca/1650/). Timing is not specified in construction contracts, but provisions are included to allow the imposition of timing restrictions and set-backs in the event that a "sensitive species" is encountered on the job site (Nichole Andre, pers. com.). Saskatchewan does not appear to similarly regulate roadside maintenance operations.

In Newfoundland and Labrador, the Environment Assessment process constrains the timing of land clearing for road construction such that it minimizes the disturbance/destruction of bird nests. For example, a recent screening report states that the Department of Transportation and Works (DTW) will conduct a pre-construction survey for migratory birds and nesting locations; nests observed within the work area will be flagged and the vegetation within the immediate surrounding area will remain undisturbed during construction activities (Transport Canada 2009). As a general rule, DTW tries to avoid clearing between April and August (John Morrissey, pers. com.). Roadsides in the province are not mowed.

British Columbia, Ontario, Saskatchewan and Newfoundland/Labrador are the only provinces that offered information about their policies and best practices that mitigate against losses of bird nests during maintenance and construction operations. Other provinces/territories may also follow such procedures, but more research is needed to explore this possibility.

Caveats and Assumptions

There are several caveats which should be taken into account in interpreting this analysis:

- obviously, the approach used is susceptible to anomalous circumstances (such as which exist for clay-coloured sparrow, and American robin);
- the density data used to calibrate the models (from the CBBC) are sparse for many species and habitats, and so may not be accurate in all circumstances;
- waterfowl data were unavailable for British Columbia, and the territories and so estimates of take for ducks are underestimated;

- there are almost certainly species other than those modelled in this paper which nest in roadside habitat, and which are therefore likely susceptible to incidental take. The total estimate of incidental take estimated for this project is likely an underestimate (notwithstanding the odd result for American robin);
- there are several elements of this approach which called for educated judgments to be used (i.e. lumping of habitat types, estimates of the relative value of roadside habitats), and adding further uncertainty to the results.

Next Steps

The results generated here should be viewed as very rough estimates of incidental take. Many assumptions were required for the modeling exercise. Estimates could be improved by:

- deriving better bird density estimates for each province/territory, including incorporation of data from the Northwest Territories / Nunavut Bird Checklist Survey and data for Prince Edward Island
- modelling each of the roadside nesting species in the list separately to improve the integrity of the incidental take estimates; applying the percent take from focal species to non-focal species within the same functional group implicitly assumes that the proportion of the population in roadside vs. non-roadside habitat is the same for both populations; this may be a particularly poor assumption for non-focal species with very large populations (e.g., American robin); in this case, the total available roadside habitat may be too small to realistically hold the same proportion of the total population
- validate/revise habitat quality multipliers with research and expert opinion
- more research into the birds that might be vulnerable to roadside maintenance in the taiga/tundra (gulls/terns, shorebirds, waterfowl)
- more research into the kinds of road maintenance that occur, if any, in Nunavut
- addition of "Arctic" habitat type to represent tundra (it is currently represented as needed in the Grassland, Shrubland and Wetland habitat types)
- more research into accounting for latitudinal differences in initiation dates, clutch size, incubation time, nestling period, fledging dates and nesting density
- research inter-annual variation in nest initiation dates to bound the simulated dates
- incorporate right-of-way width into estimating nest densities (e.g., wide rights-of-way are more likely to support waterfowl)
- more research into maintenance on permanent resource roads; take from this type of road is probably under-represented in our estimates because, at least in some provinces (e.g., Ontario), resource roads are managed by the natural resources ministry rather than by transportation; information about maintenance activities conducted by these agencies needs to be obtained
- gather information from Parks Canada about its maintenance activities in national parks
- improve estimates of area disturbed by maintenance operations by 1) obtaining information from non-respondent provinces and Nunavut, and 2) incorporating information from provinces that responded too late for their input to be used in the analysis and reporting (e.g., Ontario and Saskatchewan municipalities)

APPENDIX A: CONTACTS

A total of 32 people were contacted for information during the course of the project, most multiple times.

Contacts were asked for the following information on a provincial/territorial scale:

- what types of roadside maintenance occur in your province/territory?
- how much area (in hectares) is affected by each type of maintenance?
- when does each type of maintenance occur?

The collection of roadside disturbance information began on January 4th, 2010, and attempts to obtain good quality data continued for a full month. Early in the process of collecting these data, it became clear that many jurisdictions did not have ready access to the information we needed. In some cases (e.g., Saskatchewan, Ontario), many kilometers of road are maintained by individual Municipalities and maintenance information is simply not available at a provincial scale; getting it would require contacting many hundreds of people (e.g., there are 444 Municipalities in Ontario alone). For Ontario, the Ontario Good Roads Association agreed to circulate a simple survey to members to collect the information we needed directly from the municipalities that do the maintenance. At the time of writing, 33 responses had been received. Our contact at the Saskatchewan Association of Rural Municipalities also circulated a survey to members, and 18 responses were received. British Columbia also has a tiered road maintenance system, and information from the Districts about their maintenance activities is only available from the individual Districts. In this case, however, the proportion of roads under District management is very small relative to that managed by the Province (Angela Buckingham, pers. com.).

Roadside Disturbance Inquiries

Thirty-two people were contacted across the country, some multiple times, for information about the area of roadside maintained and the area of land cleared for road construction, and the timing of these works. The following table lists those people whose contributions moved our research forward, and summarizes their input.

British Columbia

Dianne Froese, Manager Procurement, Highway Maintenance Contracts Dianne.Froese@gov.bc.ca	roadside maintenance is performed by independent contractors who are paid a fixed price per month, and her office doesn't track their activities; maintenance is done according to general specs, but these don't dictate what time of the year or how much to mow/brush; the Districts oversee maintenance; maintenance operations must comply with all applicable federal, provincial and local laws, including the MBCA; if maintenance is going to impact birds and/or nests, a permit can be obtained from WLAP
Fred Hughes, District Operations Manager - West Kootenay District Fred.C.Hughes@gov.bc.ca	forwarded our request to Brent Bailey for response (see next entry)
Brent Bailey West Kootenay District 250-354-6517	there is no province-wide summary of maintenance operations on roads managed by the Districts; data for provincial roads should be available in an annual summary road maintenance report; contact Monique Meek in Victoria
Monique Meek Monique.Meek@gov.bc.ca	forwarded our request to Angela Buckingham
Angela Buckingham, Chief Environmental Officer, Ministry of Transportation and Infrastructure	agreed to collect the required data (both maintenance and construction); not readily available so will take some time; can only provide information for roads under Provincial management, but these constitute the vast majority of roads in BC; timing windows for maintenance and

Angela.Buckingham@gov.bc.ca	construction, during which operations are prohibited in order to protect nests/eggs/nestlings, vary depending on latitude; to date, have not received land clearing for construction information for BC
Marni Fedoruk, Project Analyst Environment, BC Ministry of Transportation and Infrastructure Marni.Fedoruk@gov.bc.ca	sent details on area maintained for roads managed by the Province; "The timing is impossible for us to track here …"; sent details on timing windows for each region: South Coast March 15 to July 31 (if works are to occur during the critical period, use a nest survey protocol) Southern Interior April 1 to July 31 Northern dates will vary depending on a project's geographic location (e.g., for Omineca in Region 7, the prohibition window is April 30 to August 1; see pg. 6 of http://www.env.gov.bc.ca/wld/documents/bmp/omineca_tw_bmp.pdf)

Alberta

Don Collins, Divisional Coordinator, Alberta Transportation (don.collins@gov.ab.ca	mowing is typically done once or twice per year on high volume highways (i.e., divided highways and busy undivided ones); mowing is done late in the season when the grasses are high; less busy roads (including unpaved ones) are typically not mowed at all; 2 additional contacts have elicited no further response

Saskatchewan

Nichole Andre, Preservation Standards Engineer, Saskatoon Ministry of Highways & Infrastructure nichole.andre@gov.sk.ca)	the Province manages >26,000 km of provincial highways; the rural municipal road system, managed by local governments throughout the province, covers nearly an additional 134,000 km (mostly gravel roads); sent requested information for both maintenance and construction; suggested contacting the Saskatchewan Association of Rural Municipalities for information about rural roads
Dale Harvey, Assistant Executive Director, Saskatchewan Association of Rural Municipalities dharvey@sarm.ca)	information on area maintained and area cleared for construction is not tracked; gave only a general sense of timing; indicated concern about asking SARM members for information about their maintenance activities because municipalities have been frustrated lately by "illogical and unnecessary cost increases and delays due to regulations and processes of Fisheries and Oceans and Navigable Waters."

Manitoba

Kimber Osiowy, Manager of Environmental Services, Manitoba Infrastructure and Transportation Ph: 204 945-2053	forwarded our request to David Block (see next entry)
David Block, Manitoba Infrastructure and Transportation david.block@gov.mb.ca	explained our data requirements on the phone and with a follow-up email (including introductory letter from EC); 2 additional contacts (by email) have not yielded any information from Manitoba

Ontario

John Small, Environmental Planner, Ontario Ministry of Transportation john.small@ontario.ca	Provincial Roads: standards for conducting mowing and vegetation control activities are generally based on the height of the vegetation in relation to visibility/traffic safety, but there is a general Special Provision (SSP 080S06) which applies to all such operations and imposes specific requirements for the monitoring/reporting of bird nesting activity; "MTO takes the migratory bird issue very seriously, and we are always looking for better ways to minimize our interference with active nesting. This week, for example, I was involved in a meeting with a falconer, whose services we are considering to deter swallows from nesting on structures slated for construction activity which would otherwise destroy their nests."
Ontario Good Roads Association Scott Butler, Policy and Research Manager Ph: 905-795-2555 x 24	recommended that we speak to Frank Hull
Ontario Good Roads Association Frank Hull, Manager of Technical Services	no central database of information about road right-of-way maintenance, or of area cleared for road construction; municipalities handle these operations on their own; gave us a contact for Wellington County as a starting point, and offered to provide more names if we decided to do a

frank@ogra.org	sample of the municipalities
Paul Johnson, Operations Manager Wellington County paulj@wellington.ca	offered to circulate a simple survey to OGRA members; did this immediately, and received 20 responses within the first 2 weeks (there are 444 municipalities in Ontario that manage 145,000 km of highway)

Quebec

Yves Bedard Transportation Quebec, Quebec ybedard@mtq.gouv.qc.ca	this person is one of the authors of the Quebec mowing report (Belanger et al. 2006); called (left message) and sent follow-up email detailing our data requirements; received 1 emailed response "I received your request for information and I hope to answer it as soon as possible and in best my knowledge but that will take some time."; followed up again by email, but to date we have received no information for Quebec

New Brunswick

Kevin Maclean, Assistant Director Highway Maintenance and Environment, Transportation Kevin.MACLEAN@gnb.ca	forwarded our request for construction information to Dale Forster, and will try to compile the information we need on maintenance by the middle of next week; to date, we have received no maintenance information for New Brunswick
Dale A. Forster, Director of Construction, New Brunswick Department of Transportation Ph (506) 453-2673, email: dale.forster@gnb.ca	to date, we have received no construction information for New Brunswick

Nova Scotia

Charles MacDonald, Executive Director Maintenance and Operations Department of Transportation and Infrastructure Renewal macdonch@gov.ns.ca	called to say he would collect the information we need, and we sent email with introductory letter; called to follow up and left message; to date, no information has been received for Nova Scotia

Prince Edward Island

Robert MacKinnon, Inventory Control Manager, Highway Maintenance, Transportation and Infrastructure ramackinnon@gov.pe.ca	received required maintenance information, including pictures of the equipment used for mowing and brushing; was directed to Stephen Yeo (Chief Engineer/Director, Capital Projects) for land clearing for construction information
Stephen Yeo, Chief Engineer/Director, Capital Projects, Transportation and Infrastructure Ph (902) 368-5105 sjyeo@gov.pe.ca	called and left message; followed up with detailed email and introductory letter; to date, no construction information has been received for PEI

Newfoundland/Labrador

John Morrissey Transportation and Works morrisseyj@gov.nl.ca	roadsides are not mowed; brushing occurs late in the season (late October through December); clearing for road construction also occurs late October through December, except in Labrador where construction seasons is short; received all required information

Nunavut

John Hawkins, Director of Transportation Policy & Planning Division jhawkins@gov.nu.ca	called and left a message; followed up with detailed email and introductory letter; called again a week later and left another message; to date, no information has been received for Nunavut

Northwest Territories

Kevin McLeod, Director Highways & Marine	forwarded our request to Adnan Aamir (see next entry)

KEVIN_MCLEOD@gov.nt.ca	
Adnan Aamir, Assistant Director Highways Operations, Department of Transportation Adnan_Aamir@gov.nt.ca	received all required information

Yukon Territory

Don Hobbis, Director Transportation Maintenance Branch don.hobbis@gov.yk.ca	received all required maintenance information from Mr. Hobbis' administrative assistant, Sonia Gay (sonia.gay@gov.yk.ca)
Robin Walsh, Director Transportation Engineering robin.walsh@gov.yk.ca	received all required construction information

General Inquiries

A total of 18 people were contacted for information about what studies have already been done on avian mortality as a result of roadside mowing/brushing. The following table lists those people whose contributions moved our research forward, and summarizes their input.

Angela Kociolek, Research Scientist Road Ecology Program Area, Western Transportation Institute Montana State University angela.kociolek@coe.montana.edu	identified Catlin and Rosenberg (2006) as the only attempt she knows to quantify incidental take due to roadside maintenance operations
Mandy Karch, Co-ordinator Ontario Road Ecology Group mkarch@torontozoo.ca	"… the lack of data points to the importance of this type of research"; OREG only has a small set of vehicle strike data
Chris C. Maguire Geo-Environmental Section, Oregon Department of Transportation christine.c.maguire@ODOT.state.or.us	"… ODOT has no data on bird mortality in the right-of-way. We know it exists, but no one has any idea about the magnitude."
Carmelita Nelson, Coordinator Roadsides for Wildlife (Minnesota) Carmelita.nelson@dnr.state.mn.us	the program provides local road authorities with information on state mowing laws with the aim of reducing disturbance of nesting wildlife "There is some research, but not enough"; sent excerpt from a book on ring-necked pheasant (Farris et al. 1977) that includes some roadside density information and a recommendation to not mow, but no data or references for mowing-related mortality; sent excerpt (literature review) from MDNR (2005) (written by Ken Varland)that contains nest success/density information for pheasant, partridge, grouse and waterfowl, but no data or references for mowing-related mortality
Keith Hobson, Research Scientist Environment Canada, Saskatoon Ph: 306-975-4102	author of incidental take report for the forestry sector; called and left message asking if he had calculated species-specific take results and, if so, would he be willing to share them for use in the land clearing for road construction portion of the roads tally; to date, no response has been received
Pierre Mineau, Head EC – Ecopathology, Ottawa Pierre.Mineau@ec.gc.ca	shared background information for Tews et al. (2009) incidental take report for the agriculture sector (related papers, breeding and population data, including regression equations used); had no data or papers on avian mortality due to roadside mowing; suggested I contact Luc Belanger to ask about his recent study of mowing impacts on roadside habitat quality in southern Quebec
Luc Belanger, Manager CWS - Population Conservation, QC Luc.Belanger@ec.gc.ca	one of the authors of recent report of mowing impacts on roadside habitat quality (Belanger et al. 2006); asked if he has any papers or data he'd be willing to share with us about bird mortality related to roadside mowing; Luc responded by forwarding request to one of the other authors (Benoit Jobin) and asking him to respond (see below)
Benoit Jobin, SAR Biologist EC – Ecosystem Conservation, Sainte-Foy	"The project aimed at evaluating bird use of roadside rights-of-way along 3 highway sections in southern Québec. We did not look at the actual effect of mowing on birds. We were looking a the effect on bird use and habitat characteristics of a reduction of the frequency of mowing .."

Benoit.Jobin@ec.gc.ca	nest searches in the roadside habitat found a single nest – mallard
Brenda Dale, Wildlife Population Biologist, EC - Population Assessment Unit, Edmonton Brenda.Dale@EC.gc.ca	sent a large number of papers/reports about various impacts on nesting success (e.g., habitat fragmentation/connectivity, vegetation structure), roadkill, invasive species, effects of haying on habitat quality, effects of roads/trails on bird community structure, and a number of papers to help determine what species nest in roadside habitats; also provided expert opinion and review of draft list of roadside nesting birds
Kathryn Lindsay, Senior Manager EC - Habitat Landscape Conservation & Biodiversity Standards, Gatineau Kathryn.Lindsay@ec.gc.ca	provided input for list of roadside nesting birds (sent Best et al. 1995), and reviewed draft list
Peter Blancher EC – Ottawa Ph: 613-998-7311 peter.blancher@ec.gc.ca	recommended talking to local birders to get information about roadside nesting birds; also recommended Brenda Dale, EC – Edmonton for input; also provided guidance with the use of the Partners in Flight Landbird Population Estimates Database
Don McNicol, Head EC - Population Assessment, Ottawa Ph: 613-949-8266 Don.McNicol@ec.gc.ca	NatureServe web site provides GIS layers for bird breeding ranges http://www.natureserve.org/getData/animalData.jsp
Connie Downes, Landbird Surveys Biologist; EC - Species Abundance and Distribution, Ottawa connie.downes@ec.gc.ca	described Breeding Bird Survey methods, and limitations for use in calculating nest densities; sent an English translation of Executive Summary for Belanger et al. 2006
Becky Stewart, Maritimes Breeding Bird Atlas Coordinator, Sackville bstewart@bsc-eoc.org	requested information about nest density estimates for savannah sparrow and song sparrow as these are not represented in the CBBC (Kennedy et al. 1999); "I'm afraid it hasn't already been summarized--all I can provide you with is the raw data from Nature Counts on our website www.mba-aom.ca"

APPENDIX B: MODELLING APPROACH

Simulation is a popular approach for estimating uncertainty when the theoretical calculations are complex. When the statistic of interest is a function of several other random variables, the variance calculations can be very difficult to solve theoretically. Monte Carlo sampling is one alternative approach for multi-dimensional numerical integration (Efron and Tibshirani 1994), which takes a brute force approach to solving such problems.

Total incidental take resulting from road maintenance activities depends on many variables, and each of these variables has uncertainty. Estimates of total take and associated uncertainty must incorporate the uncertainty in each of the component variables; we used a simulation approach to do this. As with any model, a number of assumptions were made. While no model is perfect, a simulation model is a useful tool for bounding a problem and identifying knowledge gaps. Simply proposing a model often provokes debate and helps to identify new research questions.

We followed the general framework used by Tews et al. (2009) in their assessment of incidental take associated with agricultural activities. Essentially the model compares the date of a disturbance activity to the presence of breeding birds (adults, eggs, hatchlings) within the disturbance area. In a deterministic model, all of the inputs are fixed (i.e., do not include any uncertainty). A stochastic simulation model typically uses a combination of fixed and random variables, but must have at least one random term by definition. In both cases an assumption is made about the value of the input variable and the distribution and the degree of uncertainty. However in the case of the fixed variable we are implicitly assuming that there is no uncertainty. Choosing which variables to fix and which to treat as random is somewhat subjective. However, we followed two general principles: 1) incorporate uncertainty for the terms most likely to affect variability in take; and 2) keep to simple assumptions where limited data were available, rather than trying to assess uncertainty.

The ability to estimate uncertainty is one of the key advantages to using a stochastic simulation model to estimate take. There are several different approaches to estimating uncertainty. First, if the observed results (e.g., 1000 simulation outcomes) are approximately normal or can be transformed so that they are approximately normal, then a traditional normal confidence interval can be calculated. Another approach which requires no assumption about distribution is a percentile interval. If the distribution is normal, the percentile interval will be the same as the normal confidence interval, but if the normal assumption was violated, the percentile interval is more reliable (Efron and Tibshirani, 1994).

Tews et al. (2009) incorporated uncertainty in two variables: 1) a random nest initiation date each year; and 2) a random mowing date. We also chose to include two random variables. Like Tews et al. (2009), we use a random start date for nesting. We considered incorporating uncertainty in the disturbance inputs, but ended up rejecting this idea. The disturbance data we were able to reliably obtain on the scale necessary for a Canada-wide estimate were very coarse – simply a proportion of maintenance effort by month (see Appendix C: Roads). Additionally, the timing of maintenance operations was driven not only by environmental conditions, but also by contracting cycles and contractor availability. Instead, we decided to include uncertainty in the estimate of nest density, as populations are known to fluctuate between years with environmental covariates or population cycles, and our confidence in the density estimates is not perfect (i.e., assuming zero uncertainty is unreasonable). While the various life-history variables of clutch size, sex ratio, nests per female, and egg to fledge timing are likely to vary on a local scale, we did not include uncertainty in these variables because limited data were available and we weren't interested in local scale estimates. For example, if we assume a clutch size of four eggs, but in reality some nests have three and some have five, it won't affect the calculations of take at the regional scale. We are interested in the variability in annual take at the regional scale, not how take varies from one hectare to the next.

Adding Uncertainty

Like Tews et al. (2009), we use a random nest initiation date which is drawn from a uniform (a, b) distribution with the values of parameters a, b defined by the user. Figure 2 shows an example of 1000 draws from a random uniform (91, 105) for killdeer in Ontario.

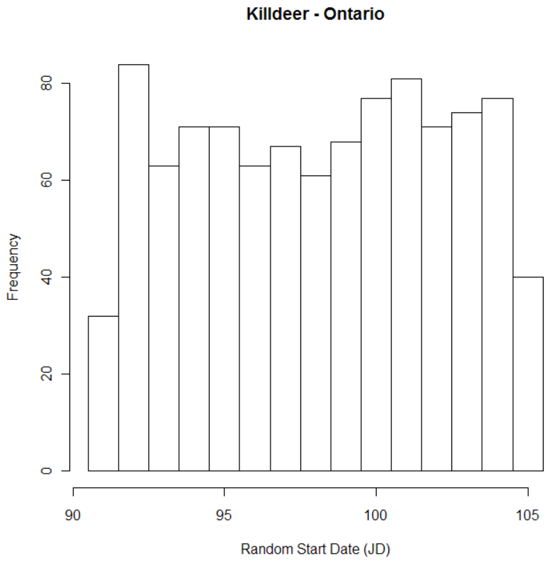

Figure 2: **Example of 1000 random nest start dates drawn from a random uniform (91,105) draws used in the simulation for Ontario killdeer. The lower frequencies at the end point are a consequence of the fact that after we take the random uniform draw, we round to the nearest Julian Day (i.e., integer) and the endpoints (91 & 105) have no probability in the continuous distribution.**

Incorporating uncertainty in the bird densities was more challenging due to the nature and quality of the data. Density estimates were obtained from Kennedy et al. (1999) as birds per km^2 by habitat type. Where data were not available we used densities from the nearest neighbouring province/territory for which there were data. Where multiple values were available, we used the mean value (see Appendix C:Birds). The non-zero estimates vary from 0.1-314 birds/km^2. While count or density data are often approximated by a Poisson distribution, this distribution is sensitive to the units (ha, km^2, 1000km^2). Simulated Poisson data generates integer values so, at lower abundances, it results in many zeros or 1s with nothing in between. This is realistic at the local scale, but is not the scale at which we have set up the simulation. For the purpose of the simulation, the parameter of interest is variation of annual density. A uniform distribution is too simple an assumption for densities, and a normal distribution is not appropriate as it may result in negative densities, especially for the lower density species. Abundance is often well approximated by a log-normal distribution (Hilborn and Mangel 1997). The lognormal distribution has characteristics similar to those of the Poisson distribution, but is continuous. By definition the X=ln(Y) ~ Normal (mu, sigma), if Y~ lognormal (mu, sigma). Where mu, and sigma refer to the mean and standard deviation of X (i.e., the normal distribution). The mean and standard deviation of Y (i.e., the lognormal distribution) are related to but not equal to mu and sigma. For each run of the simulation, we drew from a random lognormal distribution with mu=log(density).

Without better information, we assumed the variability was proportional to the mean and used sigma=0.1*log(density) (i.e., CV of 10% on the log scale). As an example, the user input density for killdeer in shrubland in Ontario was 15.4 birds/km^2. Figure 3a illustrates a realistic distribution for density (e.g., non-negative, skewed to the right), however skewed distributions are more difficult to analyze and so we can transform the data to something familiar (i.e., a normal distribution) as shown in Figure 3b).

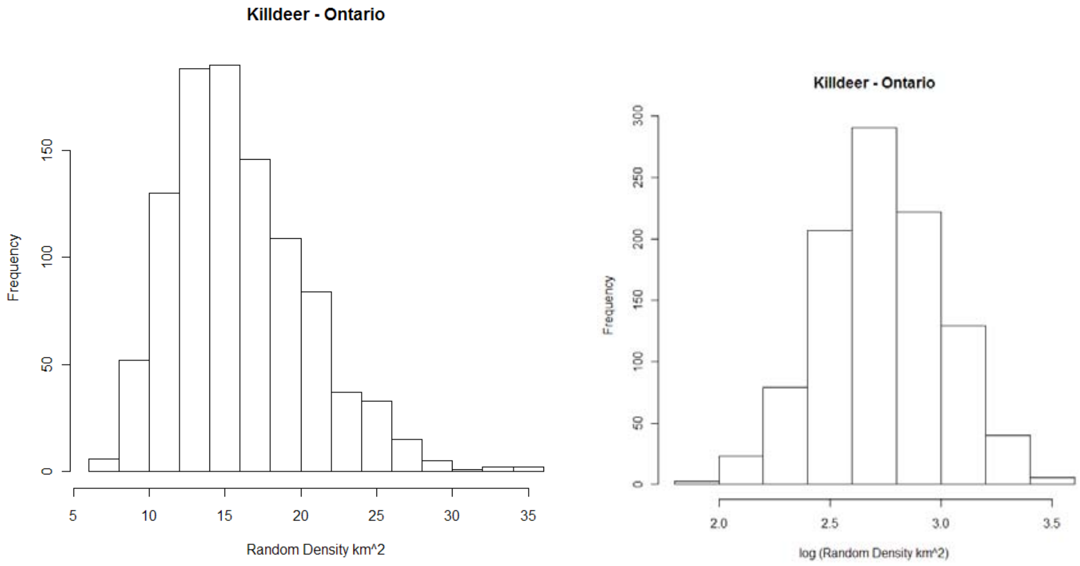

Figure 3: **a) shows 1000 draws from a lognormal distribution with mu=log(15.4) and sigma=.1*log(15.4), notice the median of the distribution = 15.4 and the distribution is skewed; b) shows the same data after taking a natural log transformation, notice the mean of the distribution = log(15.4) and the distribution is no longer skewed.**

Model Structure

The model has an annual time scale, so each run of the simulation estimates the total take for one year. The spatial scale is flexible and depends on the user defined ‘Regions’. For this report, we have treated each Province as a Region, and so the model estimates the annual take for a Province (Region). Estimates are generated separately for every focal species. Separate model inputs are required for every species and region.

The model script was written in several stand alone sections. A simple function (take.fcn) at the heart of the model calculates the annual take for a generic scenario (i.e., any land clearing activity). Several other functions calculate the necessary inputs specific to the ‘road-maintenance’ tally and loop through all scenarios of interest to the road maintenance tally. The advantage of this segmented approach is that the take.fcn function may be used to estimate the annual take for any disturbance activity; it is not just limited to ‘road-maintenance’.

Model Inputs

File name	**Description**

LifeHistoryInputs.csv	For every Species, Region, and Habitat class this file contains: o DensityKm - Density/km^2 of adult birds o ClutchSize - Mean Clutch Size o FirstEggMean – earliest breeding date (in Julian days) o rangeFirstegg – range in dates for the first egg laid o EggWindow – Length of breeding season (days between the first egg laid and the last egg laid) o EggFledge – incubation time + nestling time o P.Female – proportion of females in the population o NumNestFemale – number of nests per female (per year) o B_affected– proportion of eggs/nestlings killed given that they are present when a disturbance occurs o P_affected – proportion of the area that is actually disturbed (not currently in use, but might be useful if different types of disturbance affect areas differently
Disturb-data.csv	For every Region, this file contains: o The breakdown by month for the disturbance (i.e., % by month)
TotalRoadsRegion.csv	For every Region, this file contains: o Total_Roads - The total length of roads in km o Total_Ha_Disturbed - The total area (Ha) affected by road maintenance activity
RoadsBySpecies.csv	For every Species, Region, and Habitat class, this file contains: o Roads – the length of roads (km) in the breeding range intersecting each habitat type
Discount.csv	For every Species and Habitat class (both surrounding area and roadside): o Discount: a multiplier to account for possibility that productivity of roadside habitat may vary and may differ depending on the surrounding habitat

Script Files

Script files are shown in grey headings, with embedded functions listed in the left column and described in the right column.

Bird_functions.r	This file contains several stand-alone functions that are necessary for estimating take.
Egg.density()	Calculates the density of eggs given: adult density, clutch size, proportion of females, nests per female, and a discount value if specified. Each of these variables is user input, but initially we assumed that: the proportion of females = .5 and only 1 nest per female per year.
p.present()	Calculates the proportion of the population of eggs and nestlings are present on a given Julian day given: o Julian day, FirstEgg , EggWindow, EggFledge
Disturbance()	Function that takes in: o a vector (length 12) with the pct area affected by month o h.overlap – total hectares disturbed in the breeding area, o p.affected – set to 1 but was meant to allow for situations where only ½ the roads are mowed each year → outputs a matrix of hectares disturbed by julian day for the entire year
Area()	Calculates the hectares disturbed within each habitat, given:

	o total km of roads in the region o km of road by habitat type, within the breeding range o total hectares disturbed This function translates between the road information in km to area disturbed in hectares. We assume the disturbance is applied equally to all roads. We use the proportion of roads within the breeding area to calculate the hectares disturbed within the breeding area. We assume that the disturbance is applied to each habitat type in the same proportion that we observe roads by habitat type (within the breeding range).
Discount.fcn()	Calculates the hectares disturbed within each habitat sub-category, given: - The hectares disturbed within each habitat type, from Area() - Assumptions about roadside habitat type and quality (Table 3)
Take.fcn()	Requires: egg.density(); p.present () Calculates take for a single year for a specific: species, region, and habitat type inputs: FirstEgg,AdultDens, EggWindow, EggFledge, p.female, NPF, EggsPerNest, Rel.effort, H.overlap (hectares disturbed in breeding range), P.affected, B.affected Outputs: o Calculates take by day and reports total take for the year Note: This function can be run as a stand-alone function for any disturbance type, species, region of interest. It is not restricted to the 'road-maintenance' tally.
Bird_overall_fcn.r	This file contains a single function.
Overall.fcn	Inputs: o Region o Species o n, number of runs o noise (as a percent of the mean on the log scale) This function calculates the annual take for a species and region. Each run represents a new year. Within a year and region we assume the start date and densities are not independent. We use the same start date for all habitat types within a region, species, and year. We let the density change annually, but maintain the same relative density between habitat types. Outputs: o interim results (useful for ground truthing, de-bugging) these results display the hectares disturbed within the breeding area for each sub-category. o Simulation results – each row represents a single year or run. There is a column for each habitat sub-category in case it is of interest to compare among categories. There is also a summary column documenting the annual take across all categories. Finally there are two columns to record the two randomly generated variables: first day & density.

Birds_run.r	The function that actually runs the code & calculates take for several habitat types within a region.
	Steps: 1) set working directory 2) read in input files 3) run overall.fcn for each species and region of interest
Birds_results.r	Summarizes the simulated results: histograms, CI's
	Calculates quantile confidence intervals as well as confidence intervals assuming a log normal distribution. These are then output to a file. Histograms for the simulation results are also stored to a file.

Steps for a single run of the road-maintenance simulation (details in the table above):

1) Pull the relevant inputs (i.e., information for the current species and region) from the input files.
2) Calculate the area in hectares disturbed within each habitat class[3], using the *Area()* function.
3) Calculate the area in hectares disturbed within each habitat sub-category[4] (e.g., forest-grass, forest except grass @ roadside) and look up the associated discount multiplier; an example of interim results is shown in Table 13. Later in the model, the information in this table will be used to discount the densities in each of the habitat class sub-categories and to determine how many eggs/nestlings are present in each habitat type. This table is produced by the *Discount.fcn().*

Table 13: Example of interim results of the *Discount.fcn()* for killdeer in Ontario.

Species	hab.class	new.hab	Discount	Hectares Disturbed	DensityKm	DensityHa
Killdeer	grass	forest.grass	0.1	7364.8	10.16	0.1016
Killdeer	grass	grass.grass	1	16946.9	10.16	0.1016
Killdeer	grass	wetland.grass	1	300.7	10.16	0.1016
Killdeer	shrub	forest.shrub	0.1	7364.8	15.4	0.154
Killdeer	shrub	shrub.shrub	1	261.0	15.4	0.154
Killdeer	wetland	wetland.wetland	1	300.7	14.14	0.1414

4) Look up the relative effort, i.e., the proportion of maintenance that occurs during each month.
5) Randomly select a 'first egg date' from a uniform distribution with user input start and end dates.
6) Pick out the maximum density across habitat types within the species and region.
7) Randomly select an annual estimate of density, from a lognormal distribution based on the maximum density from the previous step (e.g., lognormal(mu=log(max.dens), sigma=.1*log(max.dens)).

---

[3] Habitat class refers to the general habitat class with which the roads intersect as identified from the GIS exercise.

[4] Habitat class sub-category refers to the general habitat class as well as the local roadside habitat. For example: forest-grass: is roadside grassland habitat that is running through a forest, whereas grass-grass: is roadside grassland habitat running through a grassland.

8) We assume that the density in different habitat types within a region are correlated (e.g., in low density years, they are all low density). Calculate the density for the other habitat types so as to maintain the same relative size. In other words, allow density to vary among years, but ensure that within a year the relative density in each habitat is maintained.
9) For each habitat type within the Region, call the generic *take.fcn()* which calculates annual take by habitat sub-category, Region, and species.

Take.fcn(), this generic function can be applied to any disturbance activity:

10) Uses the *disturbance()* function to determine how many hectares are disturbed each day of the year. Assumes that the monthly effort is spread equally among days in the month.
11) Uses *p.present()* to estimate the density of birds vulnerable to destruction each day of the year. We assume the proportion of eggs for the year can be fit by a straight line between the first egg date and the last day an egg is laid (i.e., the proportion = 0 before the first egg is laid, and =1 after the last egg is laid). This differs slightly from Tews et al. (2009) who used a regression model with real data to predict this curve. However, upon review the data were all fit adequately with a simple straight-line model which suggests that a straight-line model is a reasonable assumption to begin with. If data become available to suggest a different shape is more appropriate, it would be easy to update the code accordingly. Once the proportion of eggs by day is determined, the presence of eggs and/or nestlings for each day can be calculated based on the user input egg to fledge timing. It is then a simple matter to check any individual day to see whether or not any eggs or nestlings are available to be harmed. We assumed a fixed egg to fledge time. Although Tews et al. (2009) use a second regression curve to predict fledging behaviour, in all but one case they simply used the exact same fit as for the egg-laying; this is essentially the same as simply using a fixed egg to fledge time as we have done.
12) The number of hectares disturbed each day is then compared with the density of vulnerable birds on the same day. The daily density of vulnerable birds is multiplied by the daily hectares disturbed to estimate the daily take. The take for all days in the year is summed.
13) The annual estimate of take by habitat type, species, and region is saved and a new run begins.
14) The estimates for many runs are then summarized to provide an estimate of the total annual take and associated uncertainty. We report the median along with the 2.5th and 97.5th percentiles (Figure 4).

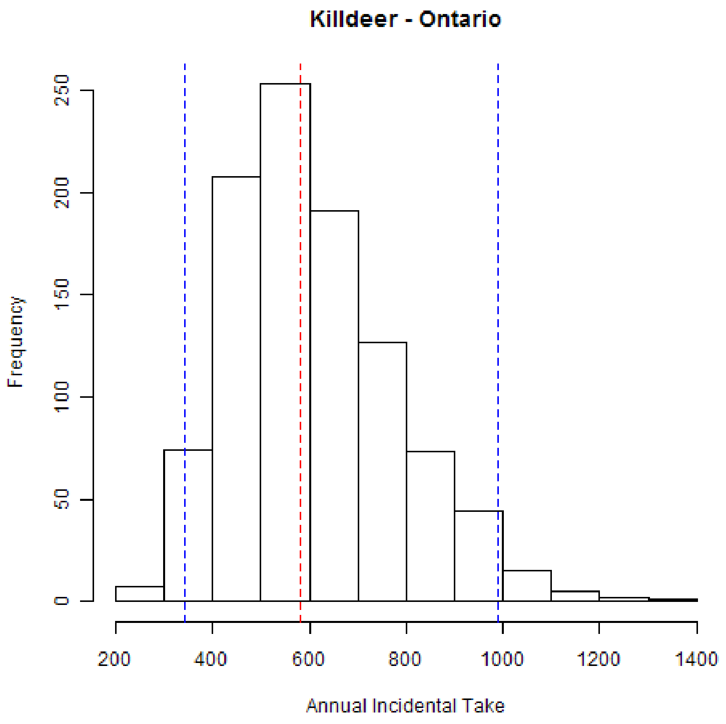

Figure 4: Summary of 1000 outcomes from the simulation model for Ontario killdeer. Each run results in an annual estimate of take. The red line represents the median or the 50th percentile from those 1000 simulations. The blue lines represent the 2.5th and 97.5th percentiles respectively.

Example of model output for killdeer

Estimates are reported by province or territory. In general, the observed results were approximately lognormally distributed, and were transformed to normalize them. Both non-parametric percentile intervals and normal confidence intervals are provided (based on the log transformed results) (Table 14). For this report we have shown the non-parametric results for each Region as they require no assumptions about distribution.

Table 14: Example of model output for killdeer. Both non-parametric percentile intervals and parametric confidence intervals (assuming lognormal distribution) are reported. LB = lower bound; UB = upper bound.

		Median & 95% Percentile intervals			Mean & 95% Confidence Intervals (assuming log(results) ~normal		
Species	Region	Median (50%)	LB (2.5%)	UB (97.5%)	mean	LB	UB
Killdeer	BC	6.9	4.8	9.9	6.9	4.7	10.1
Killdeer	Yukon	0.1	0.0	0.0	0.0	0.0	0.0
Killdeer	NW Territories						
Killdeer	Alberta	27.5	19.8	37.7	27.4	19.8	37.9
Killdeer	Saskatchewan	1282.6	802.7	2019.2	1288.5	810.6	2048.3
Killdeer	Manitoba	129.4	106.2	160.5	129.6	104.9	160.1
Killdeer	Ontario	580.2	341.3	988.9	584.8	339.5	1007.2
Killdeer	Quebec	0.2	0.2	0.2	0.2	0.2	0.2

Killdeer	NB	0.0	0.0	0.0	0.0	0.0	0.0
Killdeer	Nova Scotia	0.0	0.0	0.0	0.0	0.0	0.0
Killdeer	PEI	0.0	0.0	0.0	0.0	0.0	0.0
Killdeer	NL						
Killdeer	Nunavut						

APPENDIX C: MODEL INPUTS

Bird Breeding and Density Inputs

The following table contains the bird breeding and density data used in the simulation model. Density values by habitat type are from Kennedy et al. (1999), and breeding information is from Peck and James (1983, 1987).

Species	Prov.	Nesting Habitat	Birds /km^2	In Range?	Clutch Size	First Egg Egg (Date)	Min Incubation Time (d)	Max Incubation Time (d)	Mean Nestling Period

Road Maintenance Inputs

The following table contains the road maintenance data used in the simulation model. Values in square brackets are estimates to represent provinces for which incomplete or no information was provided. Area estimates are based on average proportion maintained for the provinces/territories for which complete data were obtained. Timing estimates assume an even distribution of effort from June through August unless otherwise stated in the **Notes** field.

Maintenance			Timing							
Location	**Activity**	**Area (ha)**	**% April**	**% May**	**% June**	**% July**	**% Aug**	**% Sept**	**% Oct**	**Notes**
British Columbia	provincial - mowing	11,852						50	50	provincial policy requires that works occur outside breeding periods so as not to disturb nests; use a nest survey protocol if works must occur within this period; timing of period shifts with latitude
British Columbia	provincial - brushing	758						[50]	[50]	includes machine and overhead brushing; timing assumed to be the same as provincial mowing
British Columbia	provincial - ditching	194						[50]	[50]	this operation would affect ground-nesters (same as mowing); timing assumed to be the same as provincial mowing
British Columbia	district	[3,246]			[34]	[33]	[33]			no data will be coming for District roads as there is no province-wide summary of their activities; could try MoE for permits (would give some info about timing)
Alberta		[108,685]					[50]	[50]		timing estimated based on input from Don Collins
Saskatchewan	provincial - mowing	4200			25	75				spring shoulder cut
Saskatchewan	provincial - mowing	28900				25	50	25		full right-of-way cut on divided highways (5900 ha) and shoulder cut for remainder (23,000 ha)
Saskatchewan	municipal	[84,651]			10	40		50		timing estimate based on input from Dale Harvey; DH circulated our survey for the RMs, but input wasn't received in time to be included

Maintenance			Timing							
Location	**Activity**	**Area (ha)**	**% April**	**% May**	**% June**	**% July**	**% Aug**	**% Sept**	**% Oct**	**Notes**
Manitoba	mowing	[38,623]			[34]	[33]	[33]			got response too late for inclusion (April 19, 2010), but the area provided in that response (38,000 ha) was very close to the estimate we used in the model; timing information was incomplete ("twice a summer on the PTH network and once in the fall on the PR Network")
Ontario	provincial	8,671	1	3	15	23	21	17	11	provincial policy requires that maintenance not disturb nests; the mitigation is not strictly a timing mitigation
Ontario	municipal placeholder	[40,260]	[1]	[10]	[21]	[21]	[19]	[20]	[8]	survey sent Feb 3; timing based on averages for 25 responses; hectares calculated by subtraction; provincial environmental standards do not apply to the municipalities
Quebec		[55,993]			[34]	[33]	[33]			no response after 2 contacts
New Brunswick	mowing	983			40	40	20			includes shrub & tree cutting
New Brunswick	ditching	72			10	35	35	20		
New Brunswick	NB Power mowing	828	2	2	8	7	13	11	8	NB Power also mows provincial roads; about 70% of the work occurs outside the breeding season; does not include urban mowing
Nova Scotia	mowing	4,450			10	40	40	10		
Prince Edward Island	brushing	465	0	0	16	28	28	28	0	brushing starts in latter half of June, and effort is evenly distributed over the 14 weeks to the end of September; the area brushed is in addition to the area mowed
Prince Edward Island	mowing	3075	0	0	40	0	20	0	40	1025 ha gets cut in latter half of June, and then it all gets cut again in mid-August, and then it all gets cut again in late September or early October for snow management; the first cut will almost certainly result in take, and the third will almost certainly NOT result in take; the second cut will probably result in some take, but only for birds that like short vegetation; have used timing to "discount" the amount of take on the second mowing

Maintenance			Timing							
Location	**Activity**	**Area (ha)**	**% April**	**% May**	**% June**	**% July**	**% Aug**	**% Sept**	**% Oct**	**Notes**
Prince Edward Island	tree trimming	15	0	0	30	0	0	35	35	tree trimming is in addition to area brushed; usually starts in June and they may skip the summer and go back to it in the fall; average 10-15 km per year
Newfoundland & Labrador	mowing	0	0	0	0	0	0	0	0	roadsides are not mowed
Newfoundland & Labrador	brushing	220	0	0	0	0	0	0	50	averaged over the last 4 years; occurs from late October through December
Nunavut		[199]			[34]	[33]	[33]			no response after 2 contacts
Northwest Territories	mowing	2750	0	0	15	30	40	15	0	includes brushing, clearing rights-of-way for highways, airports and some community roads
Northwest Territories	mowing	100	10	10	20	25	25	10	0	includes ditch cleaning, off-takes clearing and culvert repair/replacement
Yukon	mowing & brushing	1220	0	0	0	10	45	35	10	percentages are an estimate based on receipt of invoices

Avian Incidental Take due to Mining Operations in Canada

FINAL REPORT

Prepared by
ArborVitae Environmental Services Ltd.

Prepared for
Environment Canada
Western Arctic Unit, Yellowknife

December 17, 2010

Acknowledgements

The author of this project has benefited from discussions with many people in government and industry. I would like to thank the following for their contributions:

- Moss Giasson, Diane Howe, Angeline Tillmans, Steve Cranbrook, (British Columbia provincial government)
- Gavin Direm (AME BC)
- Teri Muhlbeier (Alberta Sand and Gravel Assn)
- Tim Moulding, Ann Riemer, Gordon Gray, Mike Balfour, Wes Kotyck, Rick Stilling (Saskatchewan government)
- Leslie Hymers (Ontario Mining Assocation)

Table of Contents

Executive Summary

The incidental take of birds covered by the Migratory Birds Convention Act was estimated for activities undertaken in the mining sector. The scope of the analysis covered most of common mining activities, with the exception of oil sands extraction. The assessment looked at metals and mineral extraction, aggregate mining and quarrying, and peat extraction.

There was virtually no IT identified as being associated with peat extraction because the main activity that has the potential to cause IT – the stripping of the vegetation layer at the beginning of operations – is often done in winter, while the removal of the upper peat layer to expose the mineable peat often takes place in late summer or fall. Once a bog is in production, it is inhospitable for birds and so there is no IT involved.

In the case of metals and mineral extraction, there is a meaningful level of IT. There was a considerable level of uncertainty in the estimates of IT associated with mining, so that high and low estimates were generated. The range of these estimates is very likely to include the actual value, in the opinion of the author. The variables with the greatest uncertainty were:

- The proportion of land clearing that takes place during nesting season; and
- The amount of land cleared annually, which is primarily associated with the expansion of open pit facilities.

There was a considerable variation in the estimate of the mine footprints between B.C. Saskatchewan and Ontario, however the author has considerable confidence in the numbers because all values were derived from data in the case of B.C. and from extensive discussions with government and industry staff in the sector, in the case of Saskatchewan and Ontario. Thus, if the amount of IT is near the upper end of the metal mining estimate, then pits and quarries operations produce roughly the same level of IT as metal mining does. However, the low end estimate of IT associated with metals mining is approximately 15% of the estimated IT associated with pits and quarries.

In the case of pits and quarries, two sources of IT were identified – the clearing of the land to establish or enlarge a pit (vegetation removal and overburden stripping) and the extraction of the material that can cause IT to killdeer and bank swallows. There were some data available which were used to base the estimates of bank swallow mortality on, however the author does not have a great deal of confidence in these data since they are based on a relatively small sample size. Key variables which have a significant amount of uncertainty associated with them include:

- The average number of nests in a colony;
- The number of colonies per pit;
- The percentage of pits that have operations and mortality in them in any given year; and
- Rates of colony destruction.

High and low estimates were not developed because there were data available, however as mentioned above, the author is not highly confident of the precision of the values however he believes they are within reasonable range of true values.

All Mining	Pits & Quarries	High Est Mining	High SUM	Low Est Mining	Low SUM

Table 1. Estimated Incidental Take in Canada due to Aggregate Pit Operations.

Introduction

The inadvertent destruction of birds and/or their nests and young occurs in Canada during otherwise legitimate operations in a variety of sectors, including forestry, mining, agriculture, electrical generation and transmission, fishing, roadside maintenance and road construction. Such "incidental take" is an important factor in bird conservation and management, and Environment Canada has identified a need to better understand the magnitude and significance of the issue.

This report documents a research and modeling effort to estimate the magnitude of avian mortality due to activities associated with mining across Canada, for species that breed in Canada and are covered under the Migratory Birds Convention Act (MBCA). The MBCA does not protect raptors, corvids, blackbirds, or gallinaceous birds, among others not specifically listed in the Convention.

In consultation with the Canadian Wildlife Service (CWS) project authority, the scope for this project has been defined as coverage of mining or extracting from the earth the following materials:

- metallic ore, including precious and industrial metals;
- coal and uranium;
- potash;
- diamonds;
- clay, sand, gravel and aggregates; and
- miscellaneous materials such as salt, gypsum and peat.

Oil sands mining is excluded from this study (it is part of another study in the same series).

The activities associated with mining begin with prospecting, or early stage exploration. This is often done using airborne detectors, however there are still elements of ground-based work involved, especially once a localized area has been identified as being of interest. Once a potential deposit of interest has been identified, the land is claimed or staked and further work is undertaken to determine the location, extent and grade of the deposit. There are many factors that influence the economic attractiveness of a project, and the activities associated with resource delineation and the development of a mine plan may easily take five years or more. If the deposit appears to be physically and economically feasible to extract, and a major facility is required, an environmental assessment (EA) will be undertaken. An EA is also generally required for the major expansion of an existing mine. Once the EA has been successfully completed, the facility is constructed. The nature of the facility depends on the location, characteristics of the deposit and mode of extraction, material being extracted, and such, however access roads and power lines are often constructed, as well as the physical mine site, tailings ponds and on-site processing facilities. The mine footprint is strongly influenced by whether the operation is an open pit mine or whether it is constructed underground, or is a combination of the two approaches.

Incidental take may be associated with all stages of mining, and it will most often be associated with land clearing for roads, drill site, resource sampling, and the construction of the mine site and related infrastructure. We do not here consider incidental caused by collisions with mining vehicles or mine infrastructure; those sources of IT would be considered to fall into other components of IT which have been studied separately.

In the case of aggregate pits (note there are pits for the production of sand, gravel, and aggregate, and quarries for stone – these shall collectively be referred to as aggregate pits), there is also exploratory activity but it is generally more limited and does not involve as much land clearing as in the case of metals and minerals. When a pit or quarry is developed, there is also often no environmental assessment unless it is especially large or in an especially sensitive setting. Aggregate pits are attractive nesting sites for killdeer and bank swallows also may nest in the steep sites of a pit. Therefore, the major activities that could produce incidental take associated with pits and quarries are the land clearing for pit establishment and enlargement, and activities associated with the operation of an existing pit where bank swallows have nested in the face of the pit side and/or killdeer have nested in the pit itself.

In summary, the operations considered in this analysis are:

Metals and Minerals

Activities:	Exploration, deposit appraisal, mine and mine-related infrastructure construction, and mine operation/expansion. Mine-related infrastructure may include access roads, power lines and dams, space for the facilities, and other operations (e.g. a small lake was moved to provide access to the Ekati mine in Northwest Territories). Includes coal, potash, uranium and diamonds as well as base metals and precious metals. Most of the coal, potash, uranium and diamond mines are open pit mines, but there are some that are underground (e.g. Snap Lake – diamonds; Cigar Lake - uranium) a. Similarly, just more than half of the existing and under development metal mines in B.C. are open pit; the remainder are below ground.

Aggregates

Activities:	The activities covered include the removal of the surface vegetation and overburden to start a pit or expand an existing pit and the annual operations in existing pits.

Peat

Activities:	The primary activities of interest are the preparation of the peat bogs for extraction – operations include felling any trees, creating a series of drainage ditches to dry out the peat deposit, and the stripping of the surface vegetation. In recent years, operators have begun to mix the surface vegetation into the peat deposit (excluding trees) rather than remove it. Once the peat deposit has been prepared, the peat is removed gradually over a period of years.

The mining industry, including harvesters of peat and companies that remove sand, stone, and aggregate, are required to rehabilitate spent mines, pits and quarries. There is considerable scrutiny to ensure that rehabilitation is undertaken well, and this will restore habitat to the mine site once the rehabilitation work is established. While many companies do a good job at this, this does not offset the calculation of incidental take in this study, which is concerned with the mortality caused by initial and on-going operations.

Mining operations often take place in very remote areas and mining is often seen as a means for developing or opening up an area. As indicated above, mines have substantial power needs, as well as a need for road and sometimes rail access. As a result, governments may undertake major regional infrastructure projects to support mining. There are currently several such projects being undertaken in Canada by provincial and territorial governments that are designed to provide access and power to remote areas that are known to have major mineral reserves (Canadian Intergovernmental Working Group on the Mining Industry, 2010):

- The extension of Highway 167 in northern Quebec: in its March 2009 budget, the Quebec government announced the $130 million extension of Highway 167 from Chibougamau to the Otish Mountains. The extended highway will facilitate access to projects such as Renard (diamonds), Matoush (uranium), and Macleod Lake (copper-molybdenum).
- The Northwest Transmission Line (NTL) in northwestern British Columbia: on September 16, 2009, the federal government announced a $130 million commitment to help build the 335-km NTL. Part of the remaining $274 million, from a total cost of $404 million, would come from private industry, but the Government of British Columbia, which has committed to build the NTL, would bear the largest costs with a contribution that could reach a reported $250 million. Upon completion, the NTL would improve the economics of a number of significant mining projects in northwestern British Columbia, including Galore Creek, Kerr-Sulphurets-Mitchell, and Schaft Creek.
- The Bathurst Inlet Port and Road (BIPR) project in Nunavut: this proposed deep-water port and permanent all-weather road would foster mineral exploration and production in the Kitikmeot region of Nunavut by reducing transportation costs associated with projects in this area and by lengthening the trucking season. A 50-50 joint venture between Kitikmeot Corporation and Nuna Logistics, the BIPR would be financed through a public-private partnership. Its Environmental Impact Statement is currently on hold with the Nunavut Impact Review Board. Examples of projects that could benefit from the BIPR include Hope Bay (gold); Izok Lake, NICO, Hackett River, and High Lake (all base metals); Gahcho Kue (diamonds); and Thor Lake (REE).

Because these projects are not being undertaken solely to support mining, the incidental take associated with them is considered to come under the powerline and road construction and maintenance categories, and not mining.

Basic Methodology and Analysis

OVERVIEW OF METHODOLOGY

The most widespread cause of incidental take associated with mining is the clearing of land. Because land clearing is essentially the same no matter what metal, mineral, or stone is to be mined, the same basic approach to the calculation of incidental take was followed for all components of mining. In addition, for the activities associated with aggregate pits, there were additional calculations of the within-pit mortality of killdeer and bank swallows.

This section provides an overview of the methodology for calculating the incidental take associated with land clearing for the development or expansion of mines, pits and quarries.

The key data required are:

- Area cleared per year, by broad habitat type and region
- % of area cleared during nesting season
- Density of nesting birds and average clutch size
- % of birds and eggs killed per ha of land cleared during nesting season

Mining activities are undertaken in each province and territory, but the activity is not evenly distributed across the country. In metal and mineral mining, five provinces and territories are dominant. Therefore for each mining sub-sector, detailed analyses were undertaken for the most important jurisdictions, and the results extrapolated to other provinces and territories based on the level of activity in those jurisdictions.

Bird IT mortality was calculated for two general habitat types – grassland/scrubland and forest. No data were found specifying the amount of area cleared by habitat type – while a reasonable estimate of area cleared could be developed from available data, the author used a combination of his knowledge of the country and discussion with experts to estimate the proportion of each habitat type cleared. In addition, mining for metals and diamonds, and related exploration, is being undertaken in Nunavut and Northwest Territories, and a “sub-arctic habitat” IT figure was derived for this segment of the mining sector.

In the case of metal and mineral mines, the basic calculation was to estimate the number of new mines /major mine expansions per province or territory per year, the associated footprint, and the timing of clearing and type of habitat involved. Information on new mine types and locations was readily available, and information on footprint size was obtained from government and industry personnel, and from literature in some cases.

The nature of the mining process is important from the perspective of incidental take, since the area disturbed to create and operate an open pit mine is more extensive than the area requirements for an underground mine. Moreover, in the classic strip-mining process, a strip of land is cleared, the resource excavated, and the process is repeated on successive strips of land. In contrast, the footprint for the latter type of mine is essentially established when the mine starts up, unless a future expansion takes place. Frequently mines start out as open pit operations and then convert to underground mines once the excavation depth exceeds what is feasible to be extracted from an open pit.

Estimating the incidental take associated with exploration was perhaps the most difficult task, in that there was no systematic information available on the amount of area disturbed. Where a deposit is found and there is considerable resource delineation activity, much of this will fall on what turns out to be the mine footprint, should a mine be built. Seasonality also played a major role in the assessment of impacts, as well as discussions with those in the sector regarding the introduction of low impact (and also low cost) methods of exploration.

All aggregate pits, whether they be on public or private land, must be permitted. Most jurisdictions tabulate, or have access to, the area covered by the leases, licences and permits. However, the area covered under any individual authorization is generally larger than the area of the actual pit, and there was much less information available regarding actual pit area. The Ontario Aggregate Resources Corporation (TOARC) was the only source that was located of annual new pit area. In other jurisdictions, an estimate of area cleared per annum was made based on the term of the licence. Some licence types were only valid for pits of a defined size, and where this was so, this information was considered in estimating annual new disturbance area. In general, there was less information about pits on private land, which is unfortunate since that is where the majority of pits are located.

The seasonality of operations is critical – if most land clearing takes place outside of the nesting season, there will be no incidental take, or certainly negligible amounts. There were no published data on this, and it was through discussions with industry and government staff that an estimate was determined. Reasonable data were available regarding average clutch size however little information was available regarding what proportion of the eggs, young and adult birds are killed when land is cleared during nesting season.

There were also some intangible factors that were taken into account as well. Pits on public land are more closely regulated, and can be inspected by government staff from time to time. This created the impression that operators were less likely to cause incidental take of bank swallows in pits on public land. In addition, the Ontario industry members that were contacted were all aware of the Migratory Bird Convention Act and stated that there were best practices to not operate where there were nesting colonies. Provincial government staff were also aware of the MBCA. This created the impression that at least some operators to try to avoid causing incidental take. In contrast, pit operators on private land in Alberta operate with fair less constraint. The Alberta Sand and Gravel Association was unable to collect basic operational information from its own members. In addition, none of the interviewees in the province mentioned the MBCA. This created the strong impression that there was considerable IT associated with the operation of existing pits, and a factor was added to account for this.

The within-pit incidental take of killdeer and bank swallows was based on the number of pit licences and permits (as a proxy for the number of pits), an estimate of the number of nests (killdeer) and colonies (bank swallows) in each pit and the number that are destroyed by regular extraction operations.

Incidental Take Associated with Metals & Minerals

This section covers much of what is considered to be traditional mining, namely the extraction of precious metals such gold and silver, and base metals such as copper, zinc, and nickel. Also included are coal, uranium, potash, and diamonds. There are numerous mines in Canada, and from 2004 onwards there was a tremendous amount of exploration that ended abruptly in 2008 when commodity prices declined sharply, credit became difficult to find, and the world economy went into recession. However, from the initial discovery of a potentially mineable resource, it will take a minimum of 4-6 years to develop an understanding of the nature and grade of the deposit, to formulate a mine plan and assess of the economics of the project. If the project appears to be able to generate a favourable rate of return, permitting may take several more years, since new mines and major mine expansions require environmental assessments. If a mine passes through the EA process, another 2-3 years are generally required to construct the facilities and bring it into production. Thus, mine development is a long-term undertaking, and while recessions can and do derail the process in some cases (especially when the mine developer is a small company), in most instances, once the resource has reached the permitting stage, mine development will proceed regardless of economic fluctuations.

To give the reader an idea of the number of mines, Figure 1 is a map of active mines and development projects in British Columbia, which has traditionally been among the top three mining provinces. As of 2008, there were 10 active metal mines, 9 coal mines and 35 industrial material mines in the province, with 3 metal mines and 1 coal project in an advanced stage. Another 10 metal mines, 7 coal mines and two industrial mineral quarries were in the EA process, and there were 118 major exploration projects. The more numerous early stage exploration projects are not shown.

The ratio of active mines to mines in development is low in British Columbia, since the province experienced a hiatus of exploration and development in response to the provincial government's 1997 decision to bar the development of a promising large mine in northwest B.C. due to its location in an environmentally sensitive zone. As a result, since 1997 there has been only one moderately sized molybdenum mine opened in B.C. (Chalmers, pers. comm.).

While many of the mines are underground, a surprisingly large number are open pit mines. In part this reflects the more appealing economics associated with this approach, including a more rapid mine start-up once all of the permits have been obtained. A review of the ten operating metal mines in British Columbia indicates that 6 are open pit mines, yielding minerals ranging from gold to copper to molybdenum (Source 2009 Map of Major Mining Projects in BC). Of four mines in advanced development, three are open pit projects (see Table 5).

Many of the non-metallic resources are extracted from open pit mines. Of the 9 active coal mines in the province, only one, the Quinsam Coal Mine near Campbell River, British Columbia, is an underground mine. In fact, it is Canada's last operating underground coal mine – all of the others are open pit/strip mines. Many of the uranium and diamond mines are open pit as well.

Many metal mines are also of the open pit variety, or begin with an open pit process before transitioning to an underground operation once the upper layers of the resource have been removed.

Figure 1. Insert map BC major projects mapsOF2009.pdf

There is some level of mining in almost all provinces and territories, with Prince Edward Island being the exception. Figure 2 below shows the distribution of mining expenditures by province and territory in 2008. Ontario attracted the greatest total expenditure, with 20 % of the total. Saskatchewan and Quebec were close behind, attracting 17.7 and 16.6 % of total expenditures, respectively. Saskatchewan attracted the highest share of mine development expenditures, at 20%. British Columbia attracted 13.6% of total expenditures, and the distribution of spending was notable in that 30% of all deposit appraisal expenditures were in that province. This suggests that B.C. will be the location of a greater proportion of future incidental take than its share of overall expenditures would indicate. Nunavut and Northwest Territories have attracted significant capital in recent years, and they account for 8.7 and 10.1 % of all expenditures. There is a significant gap between the expenditures in the next most active provinces – Alberta, Manitoba and Newfoundland and Labrador each attracted between 2-4% of total spending.

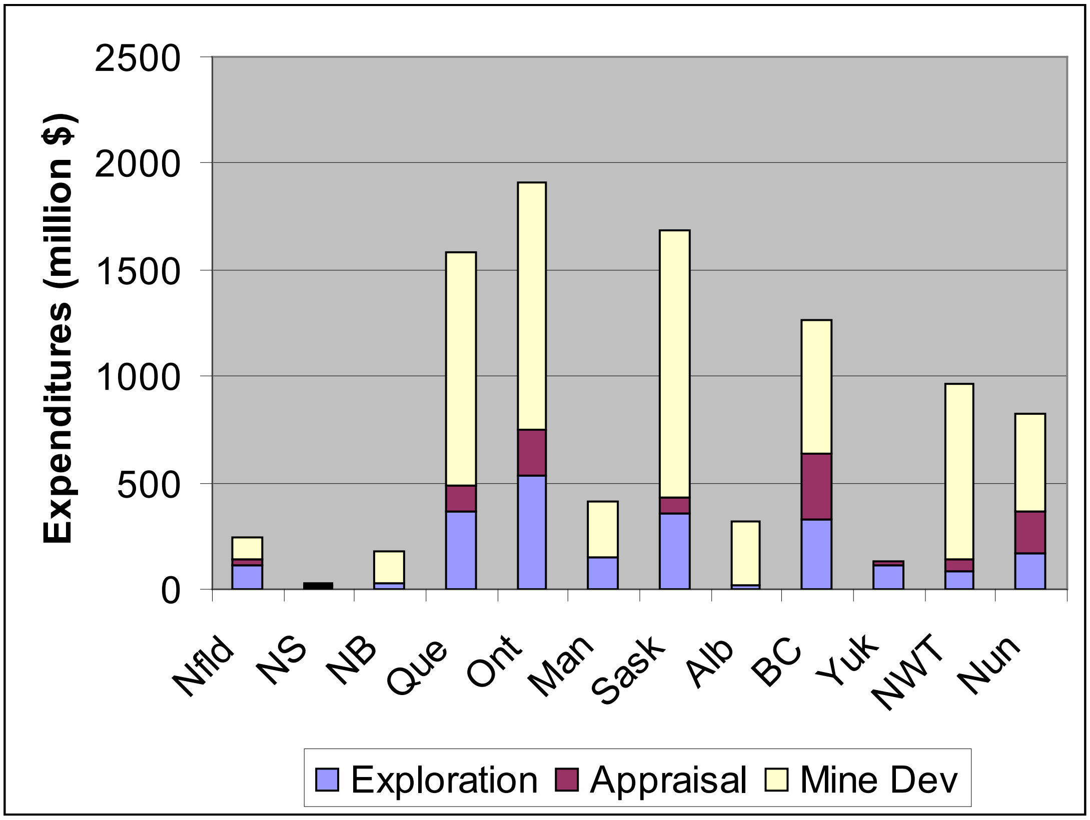

Figure 2. 2008 Mining expenditures, by major activity: Exploration, Deposit Appraisal, and Mine Complex Development (million $).

Source: The Mining Association of Canada. 2009. Facts and Figures 2009.

To optimize resource use in this project, the more detailed investigation of incidental take will focus on Ontario, Saskatchewan, British Columbia and Nunavut & Northwest Territories. The results of the analysis in Ontario will be pro-rated to estimate incidental take in Quebec, Manitoba and eastern Canada on the basis of expenditure levels, all of the provinces from Manitoba east are expected to have very similar rates of IT of similar species. The same logic is used to estimate Alberta's IT based on the estimate for Saskatchewan, and expenditures will be used to pro-rate incidental take estimates from Northwest Territories and Nunavut to apply to Yukon Territory.

The next section of the report will discuss the extent and timing of the operations that could potentially lead to incidental take. In general, there was little documentation that was obtained that provided specific information about the season in which land clearing was undertaken. However, interviews with various industry members, and what documentation was found, all pointed to winter as being when the majority of the land clearing work was undertaken, whether it was for exploration activities or for clearing land for mine development (including for associated infrastructure).

BRITISH COLUMBIA

British Columbia has historically been a major mining province but experienced a decade of minimal activity in the wake of the decision to halt a proposed mine in the Tatshenshini region. However, with changes in the provincial government and a boom in commodities, exploration in B.C. has increased significantly in (See for example Figure 1). Currently, there are 5 new mines expected to start up in the next 4-5 years (See Table 2), and these are highly likely to proceed to operating mines unless there is another economic downturn. This translates into an average of 1-1.25 new mines opening in each of the next four or five years. Most of these are open pit mines.

Mine	Company	Mineral	Mine Type	BCR
Tulsequah Chief	Redfern Resources	Gold-Zinc-Lead-Copper	Open Pit	Northwestern interior forest
Ruby Creek	Adanac Molybdenum Corp	Molybdenum	Open Pit	Northwestern interior forest
New Afton	New Gold	Copper-Gold	Underground	Great Basin
Prosperity Mine	Taseko Mines Ltd	Copper-Gold	Open Pit	Northern Rockies
Willow Creek	Western Coal	Coal	Open pit	Northwestern interior forest

Table 2. **B.C. Mines in the late stages of development and expected to open within the next 5 years.**

Data provided by the B.C. Ministry of Energy, Mines, and Petroleum Resources show that the total disturbed area associated with coal mines is 21,645 ha and the disturbed area associated with metal and mineral mines is 24,507 ha. The disturbed areas include roads, tailings ponds, waste piles, and pits, as well as other less area-intensive uses. Some rehabilitated area that has not yet been taken out of the database is also included. There are about 50 metal mines that report – approximately 25 operating and 25 closed (D. Howe, British Columbia Ministry of Energy, Mines and Petroleum Resources; pers. comm.). About 20 coal mines report – 10 active and 10 closed or in start up.

These data suggest that the average footprint of a metal mine is 0.5 sq km, and for a coal mine it is 1.1 sq km. There is considerable variation in mine size; the Kemess and Highland Valley mines are huge, each having a distance of 7 km between the mine site and tailings. (D. Howe, British Columbia Ministry of Energy, Mines and Petroleum Resources; pers. comm.). Based on these data, the author has assumed that the full footprint of the underground mine is created immediately, whereas an open pit mine starts with a 0.5 sq km. The four new open pit mines were assumed to come on stream at a rate of one per year for the next four years, and the underground mine was assumed to come on stream in 2011. All but one of the existing coal mines are open pit. Open pit mines expand their footprint over time, however the consultant did not find any information that provided a basis for estimating the average annual rate of expansion. Therefore, a high rate of 0.25 sq km /year and a low rate of 0.1 sq. km/yr were used. The author did not have data regarding the number of existing metal mines that are open pit versus underground, but estimated that the proportion ranged from 25 – 50%.

The author used the map of major projects to identify the numbers of mines in each BCR. Hobson et al. (2009) provided forest bird density information for each BCR. In the northern Rockies and northwest interior BCRs, 100% of the area cleared was assumed to be forest, while in the Great Basin BCR, 50% of the area cleared was estimated to be forest and the remainder grassland.

It is reasonable to expect that a certain amount of the clearing and development work will be done out of nesting season, but an estimate of the timing of operations was not obtained from industry sources. The author selected a range of 10 – 30% of the cleared area as a reasonable estimate, largely based on the expectation that the seasonality dynamics are similar to those described in Saskatchewan (See next section). Table 3 shows the estimated range of incidental take due to mine development in B.C., which totaled 32,453 eggs and young birds. The data elements shown in the table are for the upper estimate. The lower IT estimate, which totaled 6,722 eggs and young birds, was calculated based on the estimate that 25% of the existing metal mines were open pit (underground mines were assumed not to expand their footprint on a predictable basis), that the annual rate of expansion was 100 ha/year and on the basis that only 10% of the clearing took place during nesting season.

Parameter\BCR	Great Basin	North Rockies	NW Interior
# new mines in 2011	1	1	0
Avg mine foot print (ha)	500	500	500
# existing metal mines	5	8	12
% open pit	50	50	50
avg annual expansion (ha/open pit mine)	250	250	250
# existing coal mines	0	5	3
% open pit	100	100	100

IT estimate (lower)	869	4490	1364

Table 3. Estimated Range of Incidental Take due to Mining in British Columbia.

For this segment of the mining sector, there is assumed to be very little in-pit mortality of bank swallows and killdeer, primarily because the mines operate 365 days per year and there is no quiet time during which the birds would begin to nest. In addition, the pit walls are more likely to be rocky which would limit bank swallow nesting opportunities.

The consultant was unable to obtain any information relating to area disturbed during exploration, and there is surely some and surely some of the disturbance occurs during nesting season and causes incidental take. However there was very little information available upon which to make an estimate, and it is anticipated that mine expansion produces considerably more IT than does exploration.

SASKATCHEWAN

As of September, 2009, there were 4,969 active mineral dispositions totaling 7,079,479 ha. In addition, there were 182 active potash dispositions covering 4,313,171 ha and 6,444 coal dispositions on 4,060,390 ha, the latter having increased markedly since 2008 after a major find was made in that year in the Hudson Bay area (Saskatchewan Ministry of Energy and Resources 2009). This would seem to indicate that there is considerable potential for incidental take in the mining sector, and the large amounts of exploration and mine development expenditures would seem to further support this expectation. However our analysis suggests that incidental take within the metals and mineral portion of the Saskatchewan mining sector is minor.

There are approximately 15 operating or soon-to-be operating mines in the province. They are roughly evenly-split between open pit and underground mines. A review of active mines in the province indicates that all of the nine major potash mines are underground (two are solution mines which inject water into the underground ore; the water becomes saturated and the mineral is extracted from the water). Many of the existing potash mines are expanding significantly in light of higher prices in 2007 and especially in 2008. Three of five operating and soon-to-be-operating uranium mines are underground, and there is one underground gold mine (Seabee). There are presently three operating coal mines in Saskatchewan; all of which are surface mines.

Exploration is especially active for gold, and there is a large open pit diamond mine under development in the central part of the province that will likely reach commercial production in a few years.

Discussions with government staff indicated that the average underground metal mine has an above ground footprint of roughly 50 ha, whereas an open pit mine would typically be between 250 and 350 ha in extent. This is consistent with the estimated average mine footprint of 0.5-2 sq km provided in ArborVitae Environmental Services (2004). The potash mines are extensive and we have estimated that they might have a large footprint in the order of 200 ha. Therefore, the footprint of the existing mines, excluding access roads, is estimated at 3750 ha, as shown in Table 4. These mines have, in some cases, been operating for twenty years or more, and so there has been on average roughly one new mine per year. The average footprint is 233 ha/mine.

Mineral/mine type	# Mines	Footprint (ha/mine)	Total Area (ha)
coal	3	350	1050
uranium (open pit)	2	350	700
uranium (underground)	3	50	150

potash	9	200	1800
gold	1	50	50
SUM	18		3750

Table 4. Estimated footprint of operating mines in Saskatchewan (Incl Cigar Lake).

The run up in the price of potash that culminated in 2008 has led almost all of the potash mines in the province to expand significantly, most are in the process of doubling in size (Stilling, pers comm.), however most of the clearing associated with the expansions appears to have taken place. The consultant reviewed the Environmental Impact Statement assessments that had been prepared and approved in support of two significant potash mine expansions in Saskatchewan (K2 Tailings Management Area Expansion submitted by Mosaic Potash in January 2009; Potash Corp for its Rocanville West Expansion submitted August 2008) and a coal mine expansion project submission (Poplar River North Mine Extension Project submitted by Prairie Mines and Royalty Ltd in December 2008). These reports, provided by the provincial Environmental Assessment Branch, had varying levels of discussion relevant to incidental take.

The Rocanville West application requested permission to expand the operation by approximately 368 ha for a larger tailings management area to accommodate a proposed major increase in mining and mill capacity. The project assessment stated the following regarding the timing of disturbance: “Given the existing disturbance within the Project area from agricultural and industrial activities (e.g., brush clearing, modified pasture, and the PCS mine site including rail lines, roads, and other support infrastructures), wildlife is expected to have become habituated, or at least tolerate increased noise and activity levels. Construction for the new Service Shaft is scheduled to start before the breeding periods for sensitive species, such that they will naturally find alternate breeding areas.”

The K2 expansion covers only 60 ha, and there were no wildlife issues noted; in fact, the EIS had very little to say about biology.

One of the major exploration projects in the province is being undertaken by Shore Gold, which is in the later stages of assessing a diamond resource in the central part of the province, east of Prince Albert. The mines are expected to be open pit, at least during the first number of years, and they should be quite large. The footprint of the Star – Orion South deposits (two pits) is expected to be 5000 ha, the Orion centre and north deposits are also approximately 5000 ha, and the Taurus deposit appears to be approximately 6500 ha. These mines would likely be developed over a multi-decade period.

Because the Shore Gold project has not yet developed its official resource estimate nor has it yet applied for an environmental assessment, it is estimated that approval for the mine is at least three years away. Therefore, going forward, we will use a baseline assumption that there will be one new mine developed each year, requiring an average area of 233 ha cleared for the mine and associated facilities each year.

Discussions with Saskatchewan government staff indicate that the amount of incidental take associated with coal mine development is also limited. In spite of the interest in the coal discovery, the south western part of the province lies within the Western Sedimentary basin, where coal is abundant and it frequently can be found close to or at surface. The 2008 discovery was some depth underground and the economics are not as appealing as developing a surface mine, hence the discovery is not expected to lead to the development of any new coal mines in the province.

The three surface coal mines are in fairly close proximity and were last expanded in 1992, when a new electricity generating plant was built nearby. The mines tend to clear an area of about 1.6 km long by 100 m wide, extract the coal to a depth of some 30 m, reclaim the area and then repeat the process adjacent to the previous operation. Concerns over climate change and associated regulations and potential carbon taxes, together with a lack of new demand sources for coal in Saskatchewan, have limited interest in the development of new coal mines. While the footprint of the existing mines does gradually shift, as described above, the amount of incidental take associated with coal mining in Saskatchewan is considered to be very low. This general assessment was supported by staff from the Saskatchewan Dept of the Environment, who stated that they encourage any land clearing to take place as early in the season as possible to enable birds to find another nest location (hopefully before they have built their first nest) (Riemer, pers. comm.). And it was mentioned that land clearance for mining would not be permitted during the nesting season if there was evidence that species of concern were nesting in the area.

The consultant reviewed the Environmental Impact Statement (EIS) reports that had been prepared and approved in support of a significant coal mine expansion – the Poplar River North Mine Extension Project submitted by Prairie Mines and Royalty Ltd in December 2008. The EIS stated that the existing Poplar River North area covered 4,340 ha, and the proposed extension was to include 3,038 ha, of which 1,711 ha will be disturbed by mine activity. Project life extends from 2010 to 2039.

However, the EIS contained the following provision to minimize the potential for incidental take: "the removal of native vegetation will not be conducted between April 15 and August 15, where possible, to avoid the disruption of breeding grassland birds (SKCDC, 2007b); consultation with MOE will be conducted should salvage operations be required inside timing window restrictions …". In addition, the EIS stated that it would "conduct drainage and alteration of wetlands in the fall to minimize the impacts on amphibian breeding habitat". Finally, vehicle speeds were limited to from 50 – 80 km/hr to reduce the potential for wildlife-vehicle collisions. The set of proposals in the EIS hold out the prospect that there will be very little incidental take associated with this major expansion project.

The consultant was only able to make a rough estimate of the number of new mines or significant mine expansions planned for the province in the next five years – an average of one new mine, or the equivalent, is forecast. In other words, it will be assumed that 233 ha will be cleared annually for the mining of potash and metals. In addition, there is land clearing for coal production. The Poplar River North project will result in a significant amount of clearing – if all of the clearing is to take place within the first 15 years of the time period indicated, an average of 114 ha will be cleared annually. Because there are other strip mining operations in place, this area will be doubled to develop an annual estimate of 228 ha cleared for coal. It is assumed that all of this area will be grassland.

The information provided by various interviewees and suggested in the EIS' suggests that much of the land clearing that is done for mining takes place outside of nesting season. No quantitative estimates were obtained of what proportion of clearing activity took place in the nesting season – the consultant interpreted the relevant information to suggest that between 5 and 20% of the land clearing takes place during the nesting season, and so estimates were made using these two proportions as upper and lower limits. As indicated above, a considerable amount of IT is thought to occur in grassland ecosystems, where the majority of the coal strip mining takes place. It was estimated that 80% of the cleared area is grassland, and 20% forest. The average clutch size figure was obtained from Garrison (1999).

Table 5 shows the results of the analysis, with the high end estimate data shown in the table. The upper estimate of IT in the province due to mining is 745 birds, versus a low end estimate of 186 birds.

Parameter	Sask
avg ann mine expan (ha)	233
avg ann coal expan (ha)	228
area cleared (ha/yr)	461
% forest cleared	20
% grassland cleared	80
% area cleared in nesting season	20
forest bird density (pairs/ha)	7.5
grassland density (pairs/ha)	0.2
clutch size (eggs/nest)	4.87
% destroyed during clearing	100
IT estimate (upper)	745
IT estimate (lower)	186

Table 5. Estimated Range of Incidental Take due to Mining in Saskatchewan.

This estimate is much lower than it was in British Columbia, due to two main factors – the majority of Saskatchewan mines are underground and so do not expand on a regular basis, and the majority of the cleared area was grassland, which has a lower density of birds than forest. Finally, B.C. has more mines than Saskatchewan.

ONTARIO

There is expected to be approximately 1 new mine per year for the next five years in Ontario. Data on footprint size was rather general – the Ontario Mining Association stated that the footprint for a mine was less than five square kilometers, but it was not clear how much less. The consultant used a range of footprint size of 1.0 - 2.5 sq km.

The majority of new mine development is taking place in the north of Ontario, generally in forested lands. Using the average of Hobson et al (2009)'s nesting densities for Ontario yields an average of 7.8 nests/ha. The author could not find information on the timing of land clearing – a range of 10 to 30 percent cleared during nesting season was used.

Table 6 shows that the upper estimate of IT is almost 26,000 eggs and birds, versus a low end estimate of approximately 3,500. The considerable width of the range is due to the relatively high degree of uncertainty around some key data points.

Parameter	Ontario
area cleared (ha/yr)	2500
% forest cleared	100

% grassland cleared	0
% area cleared in nesting season	30
forest bird density (pairs/ha)	7.8
grassland density (pairs/ha)	0.2
clutch size (eggs/nest)	4.44
% destroyed during clearing	100
IT estimate (upper)	25974
IT estimate (lower)	3463

Table 6. Estimated Range of Incidental Take due to Mining in Ontario.

NUNAVUT AND NORTHWEST TERRITORIES

The Nunavut and Northwest Territories have a fairly long history of commercial mining, however a new wave was started in 1991 with Charles Fipke and Stuart Blussom's discovery of diamond-bearing kimberlites on the shores of Lac de Gras in the Northwest Territories.

Currently, there are three diamond mines in the Northwest Territories – Ekati (owned by BHP Billiton), Diavik (owned by Harry Winston), and Snap Lake owned by de Beers. Nunavut had one diamond mine – the Jericho mine owned by Tahera – that closed in 2008 as it was losing money. The Meadowbank gold mine, which began operations in February 2010, is the only operating mine in Nunavut at present (April 2010).

There was considerable exploration in both territories during the commodity boom, but both are high-cost jurisdictions and the failure of the Jericho mine well illustrates the risks associated with mining in the two territories.

Nunavut is seen as being more friendly to mining than NWT. John F. Kearney, President of the NWT & Nunavut Chamber of Mines (2010), stated that "Unfortunately, the NWT is getting a reputation as a difficult place to gain land access for exploration or to get permits for mining projects, or even for basic exploration programs, or to get permits within a reasonable time."

On April 10, 2010, the Globe and Mail ran a feature on mining in the Northwest Territories (The North scrapes bottom, Page B1). The report observed that exploration spending in the Northwest Territories had declined from $148 million in 2008 to $29 million in 2009. This was the steepest percentage decline in Canada. In sharp contrast, 2009 expenditures in Nunavut were $189 million, and $75 million in the Yukon, which is the first time in 15 years that the Yukon had seen more exploration expenditure than the NWT (NWT and Nunavut Chamber of Mines 2010).

The NWT and Nunavut Chamber of Mines (2010) continued by stating that: "For 2010, NRCAN's preliminary estimates show expected exploration expenditure in NWT at $66.3 million, which will represent more than a 100% increase from 2009. Of the [projected amount], it seems that $36 million is projected for diamond mine appraisal, and presumably represents the feasibility study on Gahcho Kue, so actual projected pure exploration is again only about $30 million. Expenditures in Nunavut for 2010 are estimated at $238 million and the Yukon again at $75 million."

There are two mines in an advanced stage of development in NWT – a rare earths mine being planned by Avalon Resources (Thor Lake) and a second diamond mine at Snap Lake (the Gahcho

Kue mine), owned de Beers. Fortune Minerals is also working on developing a gold-cobalt-bismuth project in NWT that is delayed at present due to a request by the Tlicho government for Fortune to wait until the Tlicho have completed land use planning for their traditional territory, which includes not only the mine but also a proposed road to the mine that is the main source of controversy. Given these legal issues, the timing of mine development, if it occurs, is difficult to forecast. That is all that is in the NWT pipeline for the next five years. Despite the greater receptivity to mining in Nunavut, there is probably no more than 2-3 new mines anticipated in that territory over the next five years.

There is a wide range of impact sizes associated with various mines. The existing diamond mines are very large. The Ekati mine had a footprint of 1758 ha in 2005 and that was planned to expand by 239 ha per year (Male and Nol 2005), so that it would be 2953 ha in 2010 if it kept to the planned rate of expansion. The Diavik mine has a 9 sq km footprint (www.diavik.ca). At the other end of the spectrum, the footprint of the Doris North gold project will be 41 ha of land (25.1 ha for road and building pad construction plus 15.4 ha as rock quarries) and an additional 13 ha that will be flooded by the final water level in Tail Lake.

The Meadowbank gold mine (operated by Cumberland Resources), is a complex of three open-pit gold mines located about 70 km north of the community of Baker Lake. Access to the mine from Baker Lake is by a 115 km all-weather access road. The project submission to the Nunavut Impact Review Board (NIRB), which is the equivalent of the territorial environmental assessment review board, estimated that a total of 478 ha would be developed for the mine and access road, of which 288 ha was high suitability habitat for terrestrial birds. There was little discussion in the submission regarding timing of activities or impacts on migratory birds.

Estimates of potential incidental take were developed by reviewing the environmental assessment applications for new mines /mine expansions. These provided information relating to the mine footprint, seasonality of development and operational activities, the bird species that might be affected, and measures taken to mitigate impacts. While some of the EA reports provided more complete information than others, the total amount of evidence presents a consistent analysis of potential IT impacts.

Summary of EA Reports

Other projects that have recently gone to review by the NIRB include the Doris North project, the Baffinland Iron Mine Project and the Hackett River Project.

As indicated, the Doris North is a small project. Initially, it will be set up to redevelop an existing mine, requiring little additional land clearing. However, under these circumstances, the project would only operate for a total of 24 months; the intention is that some of the neighbouring deposits would prove to be viable and would be developed. The infrastructure that would be constructed at the mine and camp sites would consist of a mill, crushing plant, fuel storage tank farm, camp, office complex, workshops, power generation plant, and sewage treatment plant, as well as an all-weather airstrip. In addition, a 4.8 km road will be built from the mine to the sealift loading area and another 5 km road will be constructed to the appropriately named Tail Lake, where the tailings would be stored.

The Doris North Environmental Impact Statement (EIS) indicated that waterfowl and upland breeding birds were among the valued ecosystem components identified at an Elders Workshop. However, because most of the road and mine pad construction will take place during winter; incidental take will be the minimal. The EIS states that “Construction rock will be placed directly onto the tundra *in winter* to protect the permafrost when building roads, laydown areas and building pads" [italics added].

The following mitigation measures were included in the EIS:

- conduct land clearing in summer for site infrastructure (*e.g.*, building pad construction and roads) outside of the breeding season (June 1 to August 1);
- prevent upland birds from nesting on mine infrastructure and man-made structures; and
- if a nest site is established and eggs are present, avoid the nest as much as possible and monitor for nest success.

The project being undertaken by Baffinland is the construction of a large, open pit iron ore mine located on north central Baffin Island. The ore would be shipped via rail to an all-season, deepwater port at Steensby Inlet. The rail line would be 143 km, and be constructed by Baffinland, as would the mine facilities and Steensby port facilities. A tote road would also be available for transport /access. This project would necessitate the construction of significant infrastructure, but discussions of impact area and seasonality could not be found in the literature.

The Hackett River project is based on deposits of zinc, silver, copper lead and gold; the proposal is for two open pits and one underground mine. The mine would make use of the proposed Bathurst Inlet Port and Road, and a 23 km access road would connect the project site with the BIPR road. Total footprint or area disturbed was not reported in the EIS, but key sources of IT were discussed and mitigation factors provided (i.e., avoid sensitive areas, try to operate outside of sensitive time periods such as breeding season). In addition, the project operator will try to avoid stray light, limit vehicle speeds and road access to minimize bird-vehicle strikes.

In March 2010, the Canadian Zinc Corporation submitted a Project Proposal Report in support of the Environmental Assessment of the proposed Prairie Creek Mine, which is a proposed redevelopment of an old mine site in NWT. The report indicated that the current 52 ha footprint of the mine will be expanded by about 6 ha to accommodate a new waste rock pile, removing an area of black spruce-lichen habitat. The main mine access road, which is 175 km long, will have some re-design to improve safety and reduce environmental impacts – the work is expected to be undertaken in the first winter. The report did not speak to incidental take but did note for the SARA and COSWEIC bird species that the truck haul would be undertaken in winter, "well outside" of the breeding period.

Territory	Mine	Footprint
NWT	Ekati	239 ha /yr expansion
Nunavut	Doris North	41 ha
NWT	Canadian Zinc	< 20 ha
Nunavut	Hackett River	Increased by 6 ha
Nunavut	Baffinland	unknown
NWT	Nico	unknown

The forecast footprint and rate of creation of that footprint are unknown for the Baffinland and Nico projects, however they are likely to be relatively large since both are open pit mines and there are new access roads also proposed. It is unknown when either mine will enter construction. If each of the Baffinland and Nico mines was to have a 1 sq km footprint created within the next five years, and the rate of expansion at Ekati remains 239 ha/year, then the expected total clearing in the two territories would be 3.25 sq km, which is equivalent to an annual rate of clearing of 650 ha/yr. This is the high estimate. On the other hand, if only one of the Baffinland or Nico mines goes ahead in the next five years, its foot print is 500 ha and the rate of expansion at Ekati slows to 100 ha/yr, then the amount of clearing will be about 220 ha/year. This is the low estimate.

Bird Species and Densities

The Meadowbank and Doris North EA submissions provided information about bird species and densities. In these studies, Lapland longspurs and horned larks were the most common birds observed. Other common migratory songbird species observed included redpolls, savannah sparrows, and America tree sparrows. The most common species of shorebirds were golden plovers, semipalmated plovers, and semipalmated sandpipers.

Assessment work undertaken for the Doris North project reported fifteen species of upland breeding birds during baseline surveys with densities ranging from 0.1 to 0.79 birds/ha. Mean density estimates for individual species ranged from 0.01 birds/ha for semipalmated plovers to 0.18 birds/ha, 0.47 birds/ha and 0.79 birds/ha for American tree sparrows, savannah sparrows, and Lapland longspurs, respectively. Seven ptarmigan were observed in the 1997 aerial survey with a mean density of 0.35 ptarmigan/km2 (0.004 ptarmigan/ha), and was consistent with the low frequency of incidental observations throughout the year. Note that no horned lark densities are estimated, despite this being the most commonly observed bird species in the Doris North area.

The waterfowl assessment work reported that during all three years, Canada geese and white-fronted geese were the most abundant birds observed. Other common species included tundra swans, long-tailed ducks, Pacific loons and sandhill cranes. Thirteen species of ducks and geese, three species of loons, one swan and one crane species were observed during baseline surveys. Estimated waterfowl density ranged from 2.5 to 10.2 birds/ha, presumably in appropriate habitat.

Of the 14 bird species considered to be breeding within the Meadowbank area, the Lapland longspur was by far the most common, averaging (i.e., of all 88 plots to date) approximately seven pairs per 16 ha plot or 43 pairs per 100 ha. Relatively few shorebirds were recorded during baseline surveys. The most common shorebird species was the semipalmated sandpiper, which was recorded in several extensive sedge meadows, often adjacent to small lakes and ponds, during the breeding bird surveys. Average number of pairs per plot was 0.2 or 1.5 pairs per 100 ha.

Densities of breeding bird species observed during the 2003 to 2005 breeding bird surveys indicate that the mine development will displace approximately 200 pairs (0.43 pair/ha) of Lapland longspurs, 60 pairs (0.12 pair/ha) of horned larks, 20 pairs (0.04 pair/ha) of savannah sparrow, 15 to 20 pairs (0.035 pair/ha) of rock ptarmigan, and minor numbers of other passerine species. The EIS focused heavily on the area of habitat loss, and devoted a relatively low amount of attention to direct mortality of birds through incidental take. It was noted that the ice-free period is only three months and so most of the construction activities are likely to be undertaken outside of breeding season.

Species	Density Data (birds /ha)	Average Reported Density (birds/ha)
Lapland longspur	0.86 (MB), 0.79 (DN)	0.83
Horned lark	0.24 (MB)	0.60
Savannah sparrow	0.08 (MB), 0.47 (DN)	0.28
American tree sparrow	0.18 (DN)	0.18

Semipalmated sandpiper	0.06 (MB)	0.06
TOTAL		1.95

If each species is assumed to lay four eggs once each year, then there are an average of 6 birds and eggs per ha during nesting season, plus some amount of waterfowl.

The high estimate is for an average area of 650 ha disturbed per year, implying that the maximum amount of potential incidental take will be 3900 birds and eggs, however it is estimated that 10% or less of the area will be cleared during breeding season, so that the maximum expected level of IT is 390 birds and eggs per year. At the low end, there is forecast to be 220 ha cleared per annum, indicating a potential IT level of 1,320 eggs and birds; 10% of this is 132. As a result, the best guess of the level of IT per year over the next five years is between 132 – 390 eggs and birds per year.

SUMMARY

The analysis of incidental take due to metal and mineral mining activities is summarized below in Table 7, and expanded to other jurisdictions to develop a national estimate. The Ontario data were scaled by a factor of 2.28 to derive an estimate for Manitoba and all of eastern Canada (including Quebec) and the Saskatchewan data was scaled up by 1.19 to capture mining in Alberta. The basis for the scaling factors was mining expenditures for 2008 (Figure 2). The data from Nunavut and NWT were increased by 25% to account for the Yukon Territory.

Jurisdiction	High IT Estimate	Low IT Estimate
British Columbia	32,453	6,722
Alberta	887	221
Saskatchewan	745	186
Ontario	25,974	3,463
Manitoba, Quebec & E Canada	59,221	7,896
Territories	488	165
CANADA	119,768	18,653

Table 7. Estimated Range of Incidental Take due to Mining in Canada.

There is considerable uncertainty in these estimates, primarily due to the lack of information about likely rates of mine footprint expansion, and the proportion of land cleared during the nesting season.

Another gap in the estimates is the lack of an estimate of incidental take due to exploration. It is anticipated that there is some IT associated with exploration, however much of the evidence obtained suggested that the largest proportion of vegetation and land clearing takes place outside of the breeding season. On the other hand, there is pressure on exploration departments to achieve results and it is likely that the dominant mindset is to undertake operations as soon as possible. Thus, if a company has determined that they would like to drill a specific target, and the first opportunity to do so is in spring, then it probably happens as soon as equipment is available and the site becomes accessible. Some of the later exploration work done to delineate a deposit would be captured in the amount of IT estimated for mines that reach production, however some initially promising deposits never become mines and any associated IT would not be captured in the estimates above. One final consideration is that it is expensive and time consuming to clear land and there have been a number of technological advances, such as heli-drills, that reduce the amount of disturbance, and the amount of associated IT. In sum, the range of IT levels shown in Table 7 is thought to be a reasonable range that probably bounds the true figure.

Incidental Take Associated with Aggregate Pits

The term “pits and quarries” refers to the excavations required to extract sand, aggregate material, gravel, stone, cement, and other such products that are typically used in construction projects. Quarries are excavations into a rock bed where the rock is the desired product – limestone, granite and quartz are typical types of rock that are quarried. The sides of the quarry are frequently very steep and rocky, except for where the access road enters into the quarry. Pits are excavations into sand, gravel or other loose material that is the desired product – the slopes may be steep but are often graded. Other metals and minerals may be mined from pits but may also be extracted from below surface mines – these materials were dealt with in the Metals and Minerals mining analysis in the preceding section.

The majority of pits and quarries in Canada are on private land located close to major population centres, which are the main markets for these materials. Most aggregate materials are fairly widely abundant and the economics encourages extraction close to the location of use – i.e. near large cities. Statistics Canada (2008) reported figures for non-metallic mining and quarrying that included potash, asbestos, diamonds, and peat, which are all reviewed in other sections of this report. An estimate was developed of the value of stone, sand, gravel, clay, gypsum, and salt production from each province and territory from the Statistics Canada data. This was challenging because the production of some material types was not shown due to confidentiality concerns, and had to be estimated. The basic process was to subtract from the total production value the values associated potash, asbestos, diamonds, salt and peat. The results showed that approximately 55% of the value of stone, sand, gravel, clay, gypsum, and salt production originated in Ontario, with 22% in Quebec, 9% in British Columbia and 7% in Nova Scotia (due largely to gypsum mining there). A considerable amount of production occurred in Alberta as well, and there were minor amounts of production in the other provinces, and negligible amounts in PEI, Saskatchewan and the three Territories. As a result, this section looks in detail at Ontario, Quebec, Alberta and British Columbia.

ONTARIO

The majority of the aggregate pits in Ontario are found on private land, especially when expressed in terms of their productive capacity. Aggregate pits on private land are required to be licensed. There are a significant number of aggregate pits on Crown land as well; tenure usually is provided through a permit. There are also what are known as Category 14 aggregate pits that are operated by forest management companies to provide aggregate for forest road construction and maintenance. Category 14 is actually an exemption from requirements that each pit be permitted – thus there are no permits for category 14 pits. However, the 2010 version of the Forest Management Planning Manual requests that all category 14 pits be identified, and thus the Forest Management Plans and Annual Work Schedules provide information on the number of pits that exist on each forest management unit. A review of these plans and reports found that many plan authors provided the information as a map product or in other formats that were not readily usable for the purposes of this project; a limited sample was obtained and used as the basis for estimation.

The table below provides a summary of key legislation and regulatory requirements.

Instrument	**Location**
Governing Mining Legislation	Aggregate Resources Act
Lead Provincial Dept	Natural Resources, Aggregates and Petroleum Resource Section. Category 14 pits are transitioning to the Ministry of Forest Section of the Ministry of Natural Resources.
Crown Land Requirements	A permit is issued under ARA. Forestry exempt under category 14.
Private Land Requirements	Either owner applies or owner consents. A licence is required under the ARA. A Class B licence permits removal of less than 20,000 tonnes/year, a Class A licence permits a greater removal.
Industry Association	The Ontario Aggregate Resource Corp collects the royalty and publishes an excellent annual statistical report. Ontario Stone, Sand and Gravel Assn
Guidance re: Migratory Birds	Section 5.00.17 in the June 1, 2007 Aggregate Resources Program Manual requires the consideration of migratory birds.

Ontario's aggregate sector is organized differently from that of other provinces in that The Ontario Aggregate Resources Corporation (TOARC) has been formed to collect royalties and other fees from the industry and distribute them back to the province. TOARC publishes an annual association report as well as an annual statistical report that handily exceed the available statistics from other provinces. Key for this study are data on the area under licence, under permit, and the amount of area under licence that is newly disturbed each year. Annual rehabilitation area is also provided.

The average area of land cleared on private lands between 2006 and 2008 was 992 ha/year. The area data were sub-divided to provide a total for each of the three Ontario regions (southern, central and northern). A disturbed area figure was not available for Crown land, however it was inferred by applying the annual rate of disturbance per area of private land under licence to the area of Crown land under permit. The resulting estimate of the area disturbed annually on Crown land was 1,380 ha/year, excluding Category 14 pits.

The majority of the provincial aggregate production takes place in southern Ontario, where the major demand centres are located. Interviews with staff of TOARC and MNR indicated that very little forest land was felled for aggregate pits in the south – the pit design would almost always avoid woodlots although some fencerows might be felled. Felling is largely done in winter. However, the overburden is primarily removed when it is unfrozen and dry, in part because the topsoil is stored and replaced during rehabilitation and removing it when wet or frozen damages its structure. As a result, the author estimated that most of the overburden removal takes place during nesting season; an estimate of 80% was used, which none of the interviewees contradicted.

In the central and northern regions, where more Crown land is cleared, it is anticipated that a minor proportion of the forest land is cleared during nesting season. Other than limits on operations caused by poor road conditions during spring breakup and the late fall, due to rain and freeze-up, there is no reason to think that there would be other sources of seasonality. Subtracting two months for each of the spring and fall operational breaks, and assuming an equal rate of clearing in the other months leads to an assumption that 25% of the forest would be cleared during nesting season.

I have also estimated proportions of forest and non-forest land cleared by general region – in the south, 95% of the land cleared is scrub, field, pasture or plowed agricultural land, and the remaining 5% is assumed to be forest. In the central part of the province – Bancroft, Pembroke, Parry Sound, North Bay – the ratio was estimated at one-third grassland and brushland and 67% forest, while in the north it is estimated at 5% grassland and brushland and 95% forest.

Category 14 Pits

So far, the analysis has not considered category 14 pits, so-called because they are authorized under category 14 of the Aggregate Resources of Ontario Provincial Standards. These pits are in fact exempted from permitting requirements so long as they meet a number of conditions, including having a size less than 3 ha. MNR staff suggested that the average site of a Category 14 pit might be 1.5 ha (Polhill, pers comm.). The Forest Management Planning process is beginning to report information about aggregate pits, however it is provided in different formats and different degrees of detail. Table 8 shows the results of a scan of 12 Forest Management Plans and/or Annual Work Schedules; data are not shown for the five plans in which no data could be found.

Forest	Number of Pits			Forest Area (ha)
	Cat 9	Cat 14	All Pits	
Dog River Matawin	78	54	132	859079
English River			61	1032771
Spruce River			21	711159
Lake Nipigon			1	900070
Nipissing	103	39	142	761985
Romeo Malette	99	14	113	629000
Crossroute			150	874000
SUM	280	107	620	5768064

Table 8. Summary of Pit Information provided in seven Forest Management Plans.

In total, there are 107 active Category 14 pits on three of the forests, which collectively cover 5.8 million hectares. On average, there is one Category 14 pit per 21,000 ha on these three forests. Applying this same ratio on the entire Area of the Undertaking, which is 38.5 million ha, leads to an estimate of 1830 Cat 14 pits. The consultants made the assumption that the Category 9 pits would be covered in the TOARC statistics, however it is not known conclusively how true this assumption is.

Category 14 pits cannot remain open for more than ten years, and if the road used to access them is to be decommissioned, the pits must be rehabilitated beforehand. Since there is little incentive to close a pit early, especially when one might need to access it in future, it is likely that most category 14 pits are kept open for a considerable length of time – perhaps 7 to 10 years. This would suggest that the average number of pits opened in a given year would be between 261 and 183. At an area of 1.5 ha each, this suggests that the average area cleared annually for category 14 pits is on the order of 392 to 275 ha (the midpoint area of 333 ha was used, of which 83 ha was assumed to be located in central Ontario and he remainder in the north). It was estimated that these pits were all created by clearing forested land.

Therefore, in 2008, the estimated area of Crown land disturbed in Ontario was 1,713 ha, or 17.1 sq km.

Derivation of Incidental Take due to Land Clearing

The calculation of the incidental take associated with land clearing for aggregate pits in Ontario is shown in Table 9. The upper rows are the estimated areas of land disturbed by region and ownership, below that the proportions of cover type are shown and the proportion of area cleared during the nesting season. Nest densities in the two habitat types were based on estimates of incidental take in Canada due to forestry operations (Hobson 2009), and on IT losses due to mowing and other mechanical operations in agricultural landscapes (Tews et al. 2009).

Parameter	Region			
	South	Central	North	TOTAL
Area Disturbed (ha/yr)				
- Crown land	2	228	1483	1713
- private land	744	148	100	992
Total	746	376	1583	2705
Prop'n grassland	0.95	0.33	0.05	
Prop'n forest	0.05	0.67	0.95	
Prop'n grassland cleared during nesting	0.8	0.8	0.8	
Prop'n forest cleared during nesting	0.25	0.25	0.25	
Forest density (pairs/ha)	7.8	7.8	7.8	
Grassl'd density (pairs/ha)	0.2	0.2	0.2	
No eggs/nest	4	4	4	
IT grassland	454	79	51	584
IT forest	291	1965	11730	13986
Total IT	745	2044	11781	14570

Table 9. Incidental take in Ontario due to land clearing for pits and quarries.

Table 9 shows that there is a total of 14,570 young birds and eggs killed due to land clearing for aggregate pits. This is a meaningful amount of IT, and the majority of it takes place on Crown land in central and northern Ontario, with relatively little taking place on private land.

Derivation of Incidental Take due to Pit Operations

In addition to land clearing, incidental take also occurs due to pit operations. The killdeer nests in open sandy or gravelly areas and is known to nest readily in gravel pits. Bank swallows nest by digging dens within the pit walls – they do not nest in quarries where the pit faces are rock. Operations in the pits during nesting season could cause incidental take of both species.

Killdeer
The key factors in estimating the IT of killdeer consisted of:

- the number of pits and quarries with killdeer nests in them, and the number of nests per pit;

- the proportion of pits and quarries that would have active operations in them during nesting season;
- number of eggs and young per nest; and
- the amount of mortality per nest caused by active operations.

Unfortunately there was little of the above data available.

The number of pits and quarries in operations was estimated to equal the number of licenses and permits. In 2008, there were 3,762 licences and 3,199 permits issued in Ontario (note that Category 14 pits are not included in these numbers). Some of the licence and permit areas are very large and probably have numerous pits, and there are some very large pits, so there may well be more than one nesting killdeer on some permits or licences. On the other hand, some pits will have no nesting killdeer.

The analysis above resulted in a mid-point estimate that there are 222 category 14 pits opened each year and if they remain open for eight years, then at any given time there will 1776 category nine pits open. In total therefore, there was an estimated 8,737 pits open at any given time. If we assume that 50% of these pits have a single active killdeer nest in them, and we estimate 4 eggs per nest, zero destruction of the adults, but complete loss of the brood if the nest is damaged, and that the harvesters operate in 25% of the available number of pits, then the amount IT caused by pit and quarry operations would be 4,369 eggs and very young birds.

Bank Swallow

The data required to estimate IT of bank swallow due to pit operations is similar to that used to estimate the IT of killdeer. The key differences are that bank swallows do not nest in quarries, since they cannot make their nesting cavities in rock, and that the swallows live in colonies that can be very large.

As in the case of the killdeer, there is relatively little information that can be gleaned from other studies. Most of the relevant information in the literature is associated with colony size, and those figures vary by region, and also have the risk of being out of date as Ontario bank swallow populations have declined significantly in recent decades; the Atlas of the Breeding Birds of Ontario, 2001-2005 reports that the Breeding Bird Survey has found an average annual rate of decline of 6.6% since 1981.

The literature describes a considerable range in colony sizes, with figures ranging from less than 10 nesting pairs to several thousand. Larger colonies tend to be found along larger river systems. Garrison (1999) provides the following data regarding average colony size:

Location	Average colony size (pairs of birds)	Citation
California	141 - 227	Lay-mon et al. 1988
Saskatchewan	8	Hiertaas 1984
Ontario	45	Peck and James 1987
Michigan	58.6	Hoogland and Sherman 1976
Alaska	64.5*	Hickman 1979
Pennsylvania and Vermont	95.4*	Spencer 1962

California	367.8*	Campbell et al 1997

Table 10. Bank swallow colony size estimates from literature.

* number of burrows. Note that Garrison (1999) cited study results indicating that from 43-77% of burrows have nests in them.

Table 10 suggests that colony sizes are quite large in California (with two citations indicating similar results), and figures from that state probably do not apply to Ontario, although Garrison (1999) did report that one colony in Ontario had 1500 pairs and Cadman (pers. comm.. 2010) reported that one big pit he visited in southern Ontario had 2000 swallows in it in numerous nesting locations. The figure from Ontario is very close to a natural average figure of 42 pairs per colony (Erskine 1979), and so an average colony size of 44 pairs of birds will be used.

The proportion of pits with colonies in it varies geographically, with higher occupancy rates in southern Ontario locations. Cadman (pers. comm.. 2010) reported that in southern Ontario (he is working in Wellington County), virtually every sand and gravel pit has bank swallows in it. In 13 pits there was a total of 27 colonies, so there is usually more than one colony per pit.

The available data did not always differentiate pits and quarries. Production statistics from TOARC (2008) indicated that between 2001 and 2008, an average of 87.5% of aggregate production in Ontario was from private land permits. In 2008, of 204 permits for above ground pits and quarries in southern Ontario, 169 (83%) were for pits, 28 (14%) for quarries and 7 (3%) for combinations of the two. Therefore, the assumption will be made that in southern Ontario, bank swallows will be nesting in 169 of the permitted areas while none will occur in the quarries or combination pit & quarry sites. Most of the Crown land licences are issued in central and northern Ontario, outside of the main range of bank swallow, and will not be considered in this estimate of bank swallow IT.

Based on the information provided by Cadman (2010), it will be assumed that there are two colonies per pit and that 20% of these colonies will be destroyed in a given year.

Therefore no. bank swallow colonies in southern Ontario aggregate pits = 169 *2 = 338.
No. bank swallow colonies destroyed = 0.2 * 338 = 68
No. of bank swallow nests destroyed = # colonies x # nests/colony = 68 * 44 = 2992
No. bank swallow eggs or young birds destroyed = 2992 * 4.44 = 13,284

This calculation is based on an average clutch size of 4.44 in Ontario (Garrison 1999), and assumes that none of the parent birds are killed.

Ontario Incidental Take Summary

In summary, it is estimated that a total of 35,000 birds and eggs are destroyed by pit and quarry operations each year in Ontario. The majority of the losses are estimated to occur in southern Ontario, where there are many pits but also large populations of killdeer and bank swallows. The estimates show that roughly 60% of the IT takes place during operations, affecting killdeer and bank swallow, and roughly 40% occurring due to forest harvesting and overburden removal practices on land as it is being cleared.

Parameter	Region

Total IT	18,398	2,044	11,781	32,223

Table 11. Estimated Incidental Take due to Ontario Aggregate Pit Operations.

There are a few key areas of uncertainty, including such factors as the timing of when the land is cleared. There are also opportunities for further refinement of key factors such as elements of the calculation of in-pit mortality of killdeer and bank swallows.

QUEBEC

Aggregate Mining in Quebec is largely regulated by the provincial Environment Department, under the legislation identified below.

Instrument	**Location**
Governing Mining Legislation	Environmental Quality Act (EQA) – Regulation respecting Pits and Quarries
Lead Provincial Dept	Ministry of Sustainable Development, Environment and Parks
Crown Land Requirements	Certificate issued by Minister of SDEP is required under section 22 of EQA
Private Land Requirements	
Industry Association	
Guidance re: Mig Birds	The regulation[1] does not permit new pits to be established within 75 m of water unless an environmental impact assessment is done that includes consideration of migratory birds.

---

[1] http://www2.publicationsduquebec.gouv.qc.ca/dynamicSearch/telecharge.php?type=3&file=/Q_2/Q2R2_A.HTM

The consultant was unable to locate information pertaining to the area of aggregate pit activity in Quebec, including the number of leases or licences and the area affected. Instead, the incidental take estimates have been derived by pro-rating Ontario incidental take numbers by the ratio of pit operation activity in Ontario and Quebec. Statistics Canada (26-226-2006) reported that the value of aggregate extraction in Quebec was 45.7% of the comparable value in Ontario – 0.457 was the factor used to scale Ontario data and apply it to Quebec.

Hobson et al's (2009) figures on forest pair density, averaged between conifer and deciduous forest types, came to 8.45 pairs/ha, somewhat higher than in Ontario.

Parameter	Region			
	South	Central	North	TOTAL
Area Disturbed (ha/yr)				
- Crown land	1	104	678	783
- private land	340	68	46	453

IT bank swallow during operations	6,071	0	0	6,071
Total IT	8,419	1,009	5,830	15,258

Table 12. Estimated Incidental Take due to Quebec Aggregate Pit Operations.

The resulting analysis shows that the incidental take associated with aggregate pit operations in Quebec is estimated at 16,086 eggs and young birds per year, of which about 6,100 are bank swallows and 2,000 are killdeer.

ALBERTA

While there is a reasonable amount of regulation of the aggregate pit sector in Alberta, there is considerably less monitoring and oversight on private land pits, which make up the majority of provincial pits (an estimated 66% of production comes from private land).

Instrument	**Location**
Governing Mining Legislation	Public Lands Act for pits on Crown land; Environmental Enhancement and Protection

	Act (private land)
Lead Provincial Dept	Sustainable Resource Development (SRD)
Crown Land Requirements	Surface Material Licences (SMC's) are for area up to 2 ha and will be operated less than 1 year. A Surface Materials Lease (SML) is issued upon request, subject to approvals, when the facility will be operating for 10 years or less, and the lease area is less than 80 acres. When the lease area > 80 acres, tenders are invited for the lease.
Private Land Requirements	Class I pits • five hectares or more in area • subject to the Code of Practice for Pits or an existing approval under the *Environmental Protection and Enhancement Act* • Pits with an existing approval must convert to a registration by November 1, 2008 • Approximately 550 Class I pits on private land in Alberta Class II pits • less than five hectares (on private land) • any size (on public land) • subject to the requirements of the Act and the Conservation and Reclamation Regulation • Estimated 1,500 to 2,000 smaller pits (private land) and 650 pits on public • Operators must comply with all requirements of the *Environmental Protection and Enhancement Act* and its regulations and Codes of Practice. In addition, they must comply with the Alberta Water Act and all other applicable provincial and federal laws.
Industry Association	Alberta Sand and Gravel Association does not have any statistics – tried to collect pit area data from its members who refused to provide it.
Guidance re: Mig Birds	The 2008 Guideline references the Migratory Bird Act and advises against tree clearing between April 1 – June 30. The Hay_Zama Lakes complex requires specific precautionary measures (see EUB Interim Directive 96-1).

Source: Alberta Sustainable Resource Development. undated. Acquiring Surface Material Dispositions on Public Land. Available at http://www.srd.alberta.ca/ManagingPrograms/Lands/

Alberta Energy provided the consultant with a list of the Surface Material Lease (SML) and Surface Material Licence (SMC) data for the province, which included the area under lease or licence and the year of issuance. The area and issuance date information was summarized. The listing contained the surface leases for the oil sands operations – these were very large leases that were readily identifiable and removed from the calculation. There were a number of smaller leases covering areas in the 1 – 15 ha range that were also issued to oil sands companies, and it was assumed that these were for pits to obtain material for road and other purposes. These leases were retained in the summary. Similarly, leases to two known peat moss extractors were also removed from the calculation.

The 2009 SMC area was 77.7 ha, and since these are one-year licences, 100% of the entire area was assumed to be disturbed (Brenda Huxley, SRD, pers comm. Mar 31).

Figure 3 shows the area associated with SMLs, which are ten-year leases for larger deposits. The figure shows the average area of each type of lease for each year of issuance. Higher than normal average lease sizes occurred in 1998 and 2003, which are years when a large aggregate company, Athabasca Minerals, obtained some very large lease areas. Because the leases have a ten-year term, the ten-year running total area is shown, as the area under lease each year. The trend lines show that not only is there a greater area under lease over time, but the average lease area size is also increasing. During the last five years (2005-09), an average of 10,100 ha was under lease.

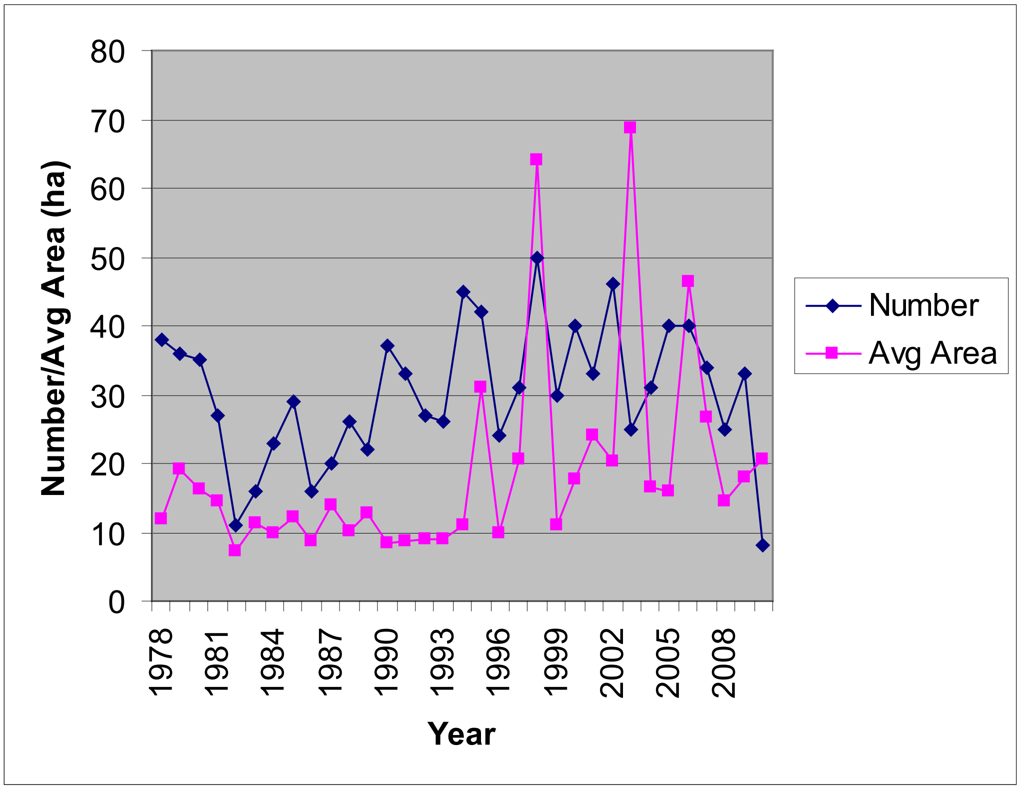

Figure 3. Number of New Leases/Year and Average Area per Lease (ha). (Source: Alberta Energy)

It was assumed that 8% of the surface area of each SML was disturbed annually – this was estimated to equate to an annual rate of extraction of ten percent reduced to provide allowance for inoperable areas, roads, buffers, etc. The calculation yields a result of 808 ha/year that is freshly disturbed, and with the area of licences added in, the total newly disturbed area per year is estimated at 886 ha/yr.

In addition to the pits on public land, there is also a significant number of pits on private land. The Alberta government does not track or report on the area of pits in private land, nor are production figures available. However, a Crown land production estimate was available for the 2007-08 fiscal year, of 14,538,181.83 cubic yards. The weight of material in a cubic yard was set at 2600 pounds, based on crushed stone weighing 2500 lbs/cubic yard, sand weighing 2500-2700 lbs/cubic yard, and gravel weighing 2700-2750 lbs/cubic yard[2]. Total provincial sand and gravel production in 2007 was preliminarily reported at 50,248,368 tonnes (Energy Resources Conservation Board and Alberta Geological Survey 2008). Therefore, Crown land production is only 34% of total provincial production, and the Crown land figures were tripled to scale them up to a provincial level.

In order to account for losses on private land pits, the Crown land IT estimated was tripled. We then increased the anticipated rate of IT per unit of private land disturbed, due to the relative lack of regulation on private land. With fewer regulations on private land, the manner in which pits are developed and exploited may be quite different than it is on Crown land. Our best guess estimate is that IT is 25% higher on private land, per unit of activity, than it is on Crown land (it is unlikely to be lower).

Parameter	TOTAL

Table 13. Estimated Incidental Take due to Alberta Aggregate Pit Operations.

The Alberta Breeding Bird Atlas (1992) shows that bank swallows are found in central and southern Alberta, but are not common in the boreal part of the province. The Atlas reports that "Colonies are fairly common in cutbanks and gravel pits in central Alberta …" and the populations may have increased locally because of human activity.

Only inferential information was found regarding the regional distribution of aggregate pits – there are considerable concentrations of them near Edmonton and Calgary as well as near the oil sands. The area data above have all of the permits issued to oil sands companies removed but there may still be some boreal pits in the summary data – it is estimated that perhaps 20% of the area may be boreal. There is also a lack of local information regarding frequency of colonization of pits, colony size and disturbance rates. If the Ontario data are applied, the estimated IT of killdeer is 168 eggs and young birds, and 26,256 bank swallows. However, Table 10 shows that in Saskatchewan, the average bank swallow colony size is eight nests – using this figure gives a bank swallow IT estimate of 4,774. Our estimate is that the true figure lies somewhere in the mid point of this range.

BRITISH COLUMBIA

British Columbia has seen considerable construction over the past decade, associated with a booming property market and most recently the construction of the Olympic facilities and associated developments (e.g. Sea-Sky Highway widening). The aggregate sector is relatively closely regulated, with the main legislation and other requirements summarized below. Authorization to develop the pit requires a pit management plan and site plan that requires current land use to be identified, final boundaries of excavation, etc. In theory this information is available to indicate the amount of various habitat types that will be removed, however it is generally not compiled.

Instrument	**Location**
Governing Mining Legislation	Mines Act
Lead Provincial Dept	Energy, Mines and Petroleum Resources
Crown Land Requirements	Most quarry and pit operations receive a Licence of Occupation to secure the land. This lasts for five years; a replacement licence valid for up to ten years may be granted. A permit under the Mines Act is required to develop and operate an aggregate pit – the application to obtain the permit is a Notice of Work and Reclamation Program.
Private Land Requirements	Either owner applies or owner consents.
Industry Association	Aggregate Producers Association of British Columbia provides a greater range of info but no statistics relevant to migratory bird incidental take.
Guidance re: Migratory Birds	Not mentioned in 2010 guide

Source: B.C. Ministry of Energy, Mines and Petroleum Resources. 2010. Guide to Preparing Mine Permit Applications for Aggregate Pits and Quarries in British Columbia. February 2010.

B.C. is divided into six regions for administrative purposes, although the number of regions is presently being reduced to five. The regions are: Northwest, Northcentral and Northeast, Kootenay, Southeast and Southwest. The web site http://www.empr.gov.bc.ca/Mining/MineralStatistics/Regional/southwest/Pages/Overview.aspx listed the number of aggregate pits in each region. A total of 470 pits were identified – in most regions, the website stated that at least the indicated number of pits were in operation. (No mention of active pits was made in any of the northern region overviews, hence this figure is assumed to apply to the southern and central part of the province, or in other words, the range of the bank swallow). The Mining and Minerals Division of the Ministry of Energy, Mines and Petroleum Resources kindly compiled data on total area disturbed by region by land use that resulted in land clearing for pits and quarries (e.g. for roads). Removing the area of pits from northeast and northwest region gave a total area of 3940 ha, of which 20% was assumed to be quarryland. It was assumed that on average, each pit is operated for five years and therefore, the annual area of newly cleared land equaled one-fifth of the total cleared land area, or 630 ha.

Hobson et al (2009) give the forest bird densities in BC as being 6.71 bird pairs/ha, which was used in this analysis.

Parameter	TOTAL
Area Disturbed (ha/yr)	630
Prop'n grassland	0.65
Prop'n forest	0.35
Prop'n grassland cleared during nesting	0.8
Prop'n forest cleared during nesting	0.25
Forest density (pairs/ha)	6.71
Grassl'd density (pairs/ha)	0.2
No eggs/nest	4
IT grassland	262
IT forest	1480
IT killdeer during operations	188
IT bank swallow during operations	31674
Total IT	33604

Table 14. Estimated Incidental Take due to B.C. Aggregate Pit Operations.

Campbell (1997) reported that the bank swallow was uncommon to rare in the coastal region and on Vancouver Island, fairly common to locally very common in the southern and central interior and the Peace Lowland, and fairly common in the sub boreal interior and northern boreal mountain regions. Of 491 colony records, the range in number of nests is 3 to 3,035, with the most common number being between 15 and 75. Campbell (1997) reviewed Garrison's study of bank swallow in southern California (average of 269 pairs per colony) and opined that colonies tend to be larger in the mountains of western North America than in the remainder of the continent. A figure of 60 pairs per colony was used in this estimate. However, this somewhat larger colony size is counterbalanced by a lower average clutch size – 3.51 for B.C. (Garrison 1999). Maintaining the assumption that there were 2 colonies per pit, and that 20% of the colonies were destroyed gives an estimate of IT of 31,675 eggs and young birds.

NATIONAL RESULTS

The amount of IT associated with aggregate pit operations in the other Canadian provinces and territories was calculated by extrapolating the total IT for the four provinces by the value of aggregate production in the remaining provinces (there is negligible aggregate production in PEI and the territories, hence the calculation covered the other provinces only).

The 2006 Statistics Canada publication 26-226 provided the value of sand and gravel production in most provinces and nationally (SIC 212323). The production from Ontario, Quebec, Alberta and British Columbia accounted for 90.3% of the national total. Thus, the IT associated with aggregate mining in the other provinces and territories was essentially 10% of the national total. The IT for the provinces not analyzed in detail was pro-rated based on relative value of sand and gravel production in Ontario and in eastern Canada and Manitoba, while the IT associated with Saskatchewan sand and gravel production was pro-rated from the Alberta rate using relative provincial value of production. The results of that calculation are shown in Table 14.

The results indicate that more than 50% of the incidental take associated with aggregate pits is due to the mortality of bank swallows, while killdeer mortality is approximately 7% of the total amount of IT. One of the main reasons why the IT due to clearing is relatively low is because the majority of trees are felled or pruned outside of nesting season, and because a substantial portion of the area cleared is grassland, which has a lower density of nesting birds than does forest.

As was described in the Ontario section, where the bank swallow determination was described in detail, there is a great deal of uncertainty regarding key variables such as proportion of aggregate pits with colonies, average colony size, proportion of pits with colonies that get operated during nesting season, and the proportion of the colony that succumbs to IT when operations take place during nesting season. Similar uncertainty is associated with the estimate of killdeer mortality.

Province	IT due to clearing	Killdeer	Bank Swallow	SUM
Nfld, NS, NB	2179	295	898	3373

Incidental Take Associated with Commercial Peat Harvesting

Peat has been mined in Canada since the early 1890's, but it was not on a large scale until the Second World War led to the disruption of shipments from Europe, especially Scandinavia, who were traditional suppliers to Canada.[3]

New Brunswick is the largest peat producing province in Canada, producing 14 million bales in 2002-03, or 45% of Canadian production (Canadian Sphagnum Peat Moss Association). There are approximately 140,000 ha of peatlands in New Brunswick; of this, approximately 70% is Crown land. The industry is concentrated in the NE part of the province. Peat mining on Crown Lands is covered by the Quarriable Substances Act.

In New Brunswick, a total of 5,448 ha were actively used for peat production, 77% of which were on Crown land (New Brunswick 2009). While the amount of area actively used is expected to gradually increase, it has been partially capped. In 2001, the New Brunswick government passed a regulation that would prevent the existing capacity of "basic" peat mining from increasing beyond the amount leased in 2001 (which included some areas that were not opened up). Since 2001, the province has only issued leases based on replacement – for additional area to be added, there must be value-added use, which is defined as producing a product with a value of at least 2x the value of basic peat.

Quebec's commercial peatlands tend to be found in the South Shore region; Quebec produced 10 million bales in 2002-03, equivalent to 32% of national production. Alberta is the third most significant producer province (4 million bales in 2002-03), followed by Saskatchewan and Manitoba (2 million bales each in 2002-03).

PEAT HARVESTING

To ready a peatland for harvesting, it must be drained which is accomplished by first removing the trees on site followed by ditching, often at 30 m intervals (Secretariat to the North American Wetlands Conservation Council Committee, 2001). Ditching is undertaken to facilitate the drying of the peat. After an interval of one or years when it is draining, the site is ready for production. The surface layer of vegetation may be removed prior to ditching, or a newer approach is the mix the surface vegetation with the upper layers of peat so that the mixture can be harvested and sold. This avoids the need to removed and dump the surface vegetation, saving expenses.

Peat is harvested using a large machine that disturbs the top layer of peat and then vacuums up the loosened dried peat. This approach was introduced in the 1960's as the cost of hand cutting and stacking became exorbitant. The average rate of mining is to remove 7 cm of depth per year (Thibault, pers comm.). The process is very weather dependent – a wet season curtails production opportunities.

The felling of the trees on a site where mining is to begin is done in winter, since that is the best time to move over the peatland, which at this point has not begun to drain. The other preparatory

---

[3] Source: www.gnb.ca/0078/minerals/Peat_Menu-e.aspx

operations, such as ditching and stripping, are most often done in the late summer and fall – the ground has to be unfrozen and drier is better than wet. Because peat harvesting has stopped by the fall, the growers also find that by doing the preparatory operations in the fall they can keep their labour force employed longer. The majority of the labour is seasonal and extending employment allows the labourers to qualify for unemployment insurance. While most interviewees said that there is some possibility that stripping or other operations would be done in the fall, very little takes place then. Once the peat bog is in production, it does not provide nesting habitat.

As a result, this study concludes that there is negligible incidental take associated with peat harvesting in Canada.

When mining has been completed in an area, there is typically a layer of peat about 3 feet deep left. Sphagnum fragments are spread on the surface and these contain seeds of all types of bog plants – within five years, there is usually a good re-growth of typical species, ranging from herbaceous to lab tea, bog rosemary, and spruce.

Avian mortality from pesticides used in agriculture in Canada

Pierre Mineau[1]

[1]Science and Technology Branch, Environment Canada, Ottawa, ON K1A 0H3

Executive Summary

A serious impediment to estimating the impact of pesticides on migratory birds is the lack of comprehensive pesticide use data. Canada is one of the few developed countries that do not collect such information. A clear recommendation of this report (and of many others) is that Canada should establish a pesticide use reporting system.

Based on areas in various crop types and on low, average and high pesticide use patterns for those same crops in the US, our best estimate for the incidental take from pesticides in Canada is between 0.96 and 4.4 million bird annually. This estimate assumes a kill rate of approximately 0.52 – 2.4 birds per hectare – the range from several industry studies carried out in typical farmland. A very approximate expert opinion is that a nest could be lost for every 4 birds killed. Given average nest success rates, this would add 50% more individuals to the above total.

The number of birds killed by pesticides has been decreasing as more toxic products are slowly being replaced for human health reasons. However, several potential impacts of pesticides, namely reproductive and indirect effects are not included in this total. Large kills of migrating birds are also not considered here although this would be more of a problem for a full accounting of pesticide impacts under US conditions than for Canada.

Approximately half of the total estimated kill is in Saskatchewan. The impact from pesticides is thought to be a clear contribution to the steep decline shown by several of grassland/farmland species. Because birds are killed on the breeding grounds, and because both adults and nests are vulnerable, this impact is proportionately higher than similar estimates derived for other sources of mortality.

Mitigation of kills is relatively easy. The products that have a high probability of causing avian mortality have been identified. In most cases, substitution products of lower toxicity to birds already exist. Regulatory inaction is the only impediment to a reduction of the direct incidental take. Chronic and indirect effects will be slightly harder to mitigate although here also, much information exists on which products carry the highest risk.

Introduction

Pesticides have been documented to impact birds in many different ways (Mineau 2003). The continued use of acutely toxic products (primarily insecticides) has been shown to kill birds regularly and predictably even when used according to label directions (Mineau 2004). This can be a dramatic event when birds are killed in large numbers on migration. Most of the time, however, birds breeding at low density on the agricultural landscape are killed singly or in small groups and these losses go unnoticed.

Pesticides can also have indirect effects, notably the removal of valuable plant and/or insect components of agro-ecosystems necessary for successful reproduction. Finally, several products have the potential to affect bird sub-lethally, especially their long-term survival and reproductive fitness.

Modern pesticides have limited ability to bio-concentrate and bio-accumulate; most are readily metabolised in warm blooded organisms. There are some exceptions (e.g. rodenticides) but we lack enough information to assess the cumulative impacts of the latter[1]. The only 'legacy' aspects of pesticides are therefore the habitat modification (simplification) aspects that form part of the indirect effects.

It is only possible to quantify the direct lethal impact on birds and even this presents special challenges. One of the main difficulties is that Canada does not systematically collect pesticide use information. Partial surveys are available for some provinces but our knowledge of what pesticides are used where and in what quantity remains fragmentary and incomplete. It is possible to draw parallels to US agriculture where good pesticide use data are available but, since insect pressure tends to increase in warmer climates, extrapolation is difficult.

There have been very few attempts to estimate the total incidental take resulting from direct intoxications following the use of toxic pesticides anywhere. Pimentel (1992), in an oft-cited study, estimated that pesticide-induced direct mortality numbered approximately 67 million per year in the U.S. He based this estimate on the fact that 160 million ha of cropland received a very heavy dose of pesticides per year (3 kg a.i./ha on average – including a number of very toxic pesticides), a breeding density of 4.2 birds per ha (from census plot data) and a conservative kill estimate of 10% of exposed birds. This estimate ignores kills of wintering birds which could be substantial (Mineau and Whiteside 2006). Also, some of the largest kills recorded in North America have been of migrants (e.g. Lapland longspurs) which would not be captured in estimates based on breeding densities in farmland.

---

[1] Research on the impact of rodenticides has been going on for several years in S&T. It should be noted however that the main species under threat are non-migratory raptorial species (e.g. buteos, eagles, various owl species).

The insecticide carbofuran (Furadan^{TM}) has been more studied than any other insecticide and can stand as the 'poster-pesticide' for bird mortality. Studies on a granular formulation of carbofuran as well as search efficiency and scavenging studies were used to provide an estimate of bird mortality per treated surface (Mineau 2005). Two major field studies, both from the U.S., were retained for purposes of extrapolation. Estimated kill rates were 3.05 birds per ha for an Iowa site (once raw carcass counts were corrected for scavenging and for unsearched areas of the field) and 15.9 per ha for an Illinois site. A third study gave estimates that were simply too high to lead to a credible wide-ranging kill rate, a full 799 carcasses of a single species (Horned lark) having been recovered from slightly more than 100 ha of crop. It was estimated that, at the height of its popularity, in the late 70s to mid 80s, this single product was killing approximately 17 to 91 million songbirds annually in the 32 million ha of U.S. corn fields alone[2].

Use of similar products in canola in the Canadian prairies was found to be correlated with regional declines in several grassland species (Mineau et al. 2005) even though the maximum proportion of treated cropland averaged about 3% and never exceeded 7% in any region of the prairies.

We will attempt to estimate the total number of birds killed by pesticides in Canada. Because most of the mortality is of breeding birds, there is an associated loss of nests and breeding potential which can be estimated also.

Methods

As mentioned above, this type of analysis is exceedingly difficult to do in Canada because we are one of the few developed countries around the world that does not assemble good pesticide use or sales statistics. In order to assess the likelihood of pesticide mortality for any given application of a pesticide, the following procedures were followed:

Estimating the toxicity of pesticides to birds

Very few species are typically tested for their sensitivity to pesticides. Interspecies differences in susceptibility can be very large. Also, the number of species tested with any given product can bias any toxicity estimate which is based on the most sensitive species tested. What is needed is a field-relevant unbiased measure of toxicity that can be used to provide a fair comparison of the kill potential of all registered pesticides. As a first step, a measure of acute pesticide toxicity for sensitive bird species ranging from 20 to 1,000 grams (a weight range that covers most bird species found dead in farm fields) was obtained by applying species sensitivity distribution techniques (Mineau et al. 2001) . A value called the HD_5 ('Hazardous Dose at the 5% tail of the species distribution') was derived. The HD_5 is

---

[2] The product is no longer registered in Europe, the U.S. or Canada but continues to be used heavily in the developing world including countries of Latin America where many of our migrants winter.

the amount of pesticide in mg of chemical per kg of body weight estimated to lead to 50% mortality in a species more sensitive than 95% of all bird species, calculated with a 50 percent probability of over- or underestimation. The HD_5 was calculated mathematically where several toxicity values exist, or extrapolation factors were applied to single (or even multiple combinations of species-specific toxicity values – see Table 1 in Mineau et al. 2001).

Estimating the proportion of cropland at risk of sustaining a bird kill

First approach

The probability of finding a bird kill (of any size) following a pesticide application was derived from models based on a large sample of empirical field studies where known insecticides were applied and searching was carried out to detect casualties. Models were developed for field and orchard crops separately. Because few of the studies were quantitative in nature, logistic modeling was used and the output of the models is the likelihood that a kill of undefined size would occur and be found assuming an adequate search effort[3]. Aside from the HD_5 values, the models uses application rate, as well as physico-chemical constants such as octanol-water partition coefficient, molecular weight and size as well as the ratio of rat oral to dermal data, when available (details provided in Mineau 2002). Independent validation of the model for a sample of studies in field crops indicate that better than 81% of studies were correctly classified – as to whether they gave rise to mortality or not.

Using these models, Mineau and Whiteside (2006) analysed the insecticide use pattern for all U.S. crops on a State by State basis. They provided a minimum, weighted average and maximum proportion of each crop area where bird lethality was expected. It is possible to estimate the proportion of Canadian cropland at similar risk if we assume that pesticide use conditions in at least one of the censused U.S. States correspond to how the crop is treated in Canada.

Crop data for Canada was obtained from the 2006 quinquennial census of agriculture (Statistics Canada 2009).

Inadequate and incomplete recording of seed treatment chemicals as well as our inability to fit these uses into existing risk models means that they are essentially ignored in the estimates.

Second approach

Models developed in Mineau (2002) and described above were modified to take into account the addition of a few more field studies and a recent re-evaluation of all the component agricultural studies by a panel of four evaluators mandated by

---

[3] Carcass searches in most field studies employ lines of searchers systematically covering the field area as well as search dogs on occasion. The probability of seeing kills otherwise is negligible.

the European Food Safety Authority (EFSA 2008). Mineau (2002) argued for the importance of dermal exposure when assessing the field data; however, because of the uncertainty surrounding dermal exposure to new classes of insecticides for which field studies do not exist (EFSA op. cit.), the basic risk model was modified to consider only the toxicity of the various pesticides to birds (here the HD_5) in arriving at a probability of kill.

This simpler single model was applied to a summary of Canadian insecticide use assembled from disparate provincial sources of information on pesticide sales or use (Brimble et al. 2005). Pesticide sales or use data were not available for Québec (because several active ingredients are combined before the data are released) or for Saskatchewan. It should be noted that the quality of the data emanating from the other provinces is uneven and of unproven quality.

Because some of this survey information was already dated in 2005, several listed insecticides are no longer registered today. These were removed from the list. Without any knowledge of their replacements, a full accounting of insecticide use in Canada is not possible and whatever kills are estimated must be under-estimates.

Application rates per hectare were obtained from pesticide labels. In reviewing available labels for each active ingredient, we tried to retain modal application rates – those rates that came up the most frequently, especially foliar rates of application associated with large area field crops. Mean application rates were calculated when modal rates were not evident (Appendix 2).

Most or all seed treatment pesticides currently registered and marketed in Canada were not included in the provincial totals. The risk from several of these compounds appears to be high in Canada (Smith 2006) although no field studies have been carried out and these uses therefore fall outside of the field models created to estimate the risk of mortality. Our inability to adequately assess the risk to birds from the growing use of seed treatments is a serious regulatory issue – as well as a serious gap for the purpose of this exercise.

Estimating the number of birds involved in a kill

As mentioned earlier, the majority of field studies provide a very poor basis on which to base a quantitative estimate of kills. Several field studies were carried out with carbofuran – either the liquid or granular formulations; in a few cases, alternative pesticides were tested as well under the same conditions (FMC 1989a,b summarised in Mineau 1993). Kills resulting from the use of the granular formulation were already quantified for the U.S. and reported above. Because the silica-based granular formulation of carbofuran is a rather unusual product (because of the combination of high toxicity and a granule base very attractive to birds) and is no longer registered in Canada, the studies reporting on spray applications will be used instead.

One substantial advantage of using these studies to try to arrive at a quantified estimate of a 'typical' kill is that carbofuran, being a carbamate insecticide, kills more quickly than most other toxic insecticides. With several other products, birds are more likely to ingest a lethal dose but die later away from the field area, or ingest a dose which might have been sub-lethal had the bird not been subject to delayed mortality as a result of cold, food stress or predation (reviewed in Mineau 2003). Even with this rapid mode of action, some birds have been shown to leave the field area and die in surrounding fields and field margins. Also, these studies were carried out by the same group of experimenters under similar conditions, search plots were cleared of old carcasses prior to the study to minimise any confusion over the attribution of mortality to the pesticide and search and scavenging rates were well assessed in each plot by means of 3-day old black chicks of domestic chickens – a reasonable stand in for small to medium sized songbirds.

Table 1 below gives raw unadjusted rates of carcass counts for these carbofuran and associated[4] field trials. In every case, the search area was divided equally between the field and surrounding non field habitat. Unlike the granular formulation, the liquid formulation of carbofuran is still registered in Canada. Chlorpyrifos and methomyl are also two major use insecticides in this country.

Table 1. Uncorrected kill rates for several pesticide field studies carried out under standardised conditions of searching employing teams of observers and search dogs.

Pesticide	Crop	Location	Uncorrected kill rate (carcasses/searched ha)
carbofuran	corn	Nebraska	0.43
carbofuran	corn	Texas	0.53
carbofuran	alfalfa	Kansas	0.47
carbofuran	alfalfa	Oklahoma	0.22
chlorpyrifos	alfalfa	Kansas	0.22
Chlorpyrifos and methomyl	alfalfa	Oklahoma	0.53

Table X. Uncorrected raw kill rates observed in several field studies reviewed in Mineau (1993).

Carbofuran is quite acutely toxic to birds so extrapolations based on this pesticide might be considered worst case. However, plots treated with chlorpyrifos, an insecticide of much lower acute toxicity to birds had similar levels of mortality. Also, because our methods of estimating the number of kills in Canada already factor in toxicity to estimate the probability that a kill will occur, it could be argued

---

[4] Alternate pesticides were applied to control plots in these studies.

that the actual body count per hectare, when a kill does occur, is less a factor of toxicity and more dependant on the number of birds frequenting the field and potentially exposed.

Search rates and scavenging were measured in detail in these studies[5]. Plot by plot estimates vary widely but overall means are provided below for the combination of all habitats surveyed in the studies: fields, field margins and roads for the corn study; fields and field margins in the case of the alfalfa studies (Table 2).

Table 2. Measured rates of search efficiency and scavenging.

Pesticide	Crop	Search efficiency averaged among all habitat types	Scavenging rate averaged among all habitat types	Combined detection rate
corn	Nebraska	0.22	0.19	0.18
corn	Texas	0.37	0.26	0.27
alfalfa	Kansas	0.50	0.16	0.42
alfalfa	Oklahoma	0.46	0.21	0.36

These are one time search and scavenging correction estimates. In theory, repeated visits to the site (daily searches for a week were carried out in the studies outlined above) increase the probability of finding carcasses not found during a previous search. However, because of the skewed nature of carcass life expectancies (fresh carcasses disappear quickly, older carcasses cease to be of interest to scavengers), attempts to calculate overall probabilities of detection by using mean carcass ‘life-expectancies’ have generally been unsatisfactory and heavily biased (Smallwood 2007). A carcass missed on the first day of searching and subject to a further 24 hours of scavenging has a rapidly decreasing probability of being detected on subsequent days. Also, if a carcass was not found on the first search day, it is likely well hidden and the probability that it will be found on subsequent days is considerably less than the average search rate would suggest. For these reasons, simple one time estimates were used here to estimate the number of birds that would have gone undetected in the field studies (Table 3).

---

[5] The help of Mélanie Whiteside is gratefully acknowledged for extracting the relevant information from lengthy industry reports.

Table 3. Corrected kill rates for several pesticide field studies.

Pesticide	Crop	Location	Uncorrected kill rate (carcasses / searched ha)	Corrected kill rate (carcasses per ha)
carbofuran	Corn	Nebraska	0.43	2.4
carbofuran	Corn	Texas	0.53	2.0
carbofuran	alfalfa	Kansas	0.47	1.1
carbofuran	alfalfa	Oklahoma	0.22	0.61
chlorpyrifos	alfalfa	Kansas	0.22	0.52
Chlorpyrifos and methomyl	alfalfa	Oklahoma	0.53	1.5

I propose to use the range of mortality rates calculated from these studies to quantify mortality when the risk model predicts that mortality will occur. For example, if the logistic model predicts that a certain pesticide application has a 0.50 probability of mortality based on the combined sample of field studies, and assuming that the pesticide is applied to 100,000 ha, the low and high estimates of mortality will be:

Low: 0.50 * 100,000 ha * 0.52 carcasses/ha
High: 0.50 * 100,000 ha* 2.4 carcasses/ha

The reader is reminded that these studies used for this quantification ignore any kills of migrants which, as mentioned earlier, can be substantial. Secondary poisoning of scavengers is also not included nor is delayed mortality or reproductive effects. It will be assumed that all mortality is on adult birds and very rough estimates of the number of failed nests will also be made.

Which species are killed by pesticides?

A total of 50 agricultural field studies with demonstrated avian mortality[6] were tallied in order to identify which species are most often killed in the course of pesticide applications. The sample of studies was fairly broadly based, both in terms of the crops sampled (table 4) and the locations of the fields (table 5). The number of studies in which species were found dead is given in table 6. Not all of these species are relevant to Canadian conditions but they were left there because they can provide information on ecologically equivalent species.

---

[6] Most of these studies are proprietary industry studies submitted to the U.S. government. Those dealing with spray applications (29 studies) were reviewed in Mineau 2002. A sample of studies on granular formulations (21 studies) was similarly obtained and reviewed.

Table 4. The number of study-crop combinations for which mortality was detected and which were used in the species tally presented in table 3.

Crop	No. studies

Species most frequently implicated in kills are those that are cosmopolitan, closely associated with agriculture and reasonably common; e.g. mourning doves, several sparrows, horned larks and meadowlarks, robins, house sparrows and several blackbird species. However, the sheer diversity of birds potentially killed by pesticides is impressive and suggests that toxicological or ecological susceptibility are less important than being simply in the wrong place at the wrong time. These studies were all carried out in the breeding season and underestimate the impact of pesticide use on migrant species or wintering species. Kills during the breeding season are more relevant to Canadian conditions because of the limited use of pesticides outside the breeding season. A fuller account of species killed by pesticides can be found in the incident record (http://www.abcbirds.org/abcprograms/policy/pesticides/aims/aims/index.cfm). The list also does not include species that are preferentially killed by pesticides on non-agricultural sites; e.g. golf courses and other turf areas. A number of waterfowl species fall in this group. Finally, birds of prey are underrepresented because they typically die well away from application sites. These are not migratory birds so no effort will be made to quantify the kills but Mineau et al. (1999) provided an extensive review of recorded incidents for both Canada and the U.S.

Results

First approach

Based on US pesticide application data, the following are estimated kills for Canada assuming that each censused crop is grown with the least risk to birds shown by any US State, an average risk to birds based on the weighted average of the 50 conterminous US States or the maximum risk to birds based on the worst State profile for each individual crop. Details for each crop are given in Appendix 1. High and low estimates based on the two kill rates calculated above are summarised in table 7 below.

Table 7. Summarised results of predicted incidental take from pesticides. This method assumes that the probability of kill for each commodity will be within the range shown for the State by State US analysis of kill probabilities as calculated in Mineau and Whiteside (2006). See appendix 1.

	Canadian growers grow the crop like growers in the 'best' US State	Canadian growers grow the crop like growers in the 'worst' US State	Canadian growers grow the crop like growers in an average US State
Low kill rate per ha	220,160	4,473,161	960,011
High kill rate per ha	1,016,121	20,645,358	4,430,819

It is unlikely that we grow each and every crop with less impact on birds than any of the 50 conterminous US States. Assuming that we fall around the average US State in terms of use quantities and avian toxicity of product choice for each commodity, this would place mortality at between 0.96 and 4.4 million birds annually under current (2000-2003) conditions.

It is possible to parse out the expected mortality on a province by province basis based on crop data for each province. Table 7 shows the 6 kill estimates for each province and table 8 shows what percentage of the total Canadian kill each province represents under the same assumptions.

Table 6. The estimated kill by province under varying assumptions of commodity-specific risk to bird (based on the 50 conterminous US States) and a low and high mortality rate as detailed above. (Numbers will not add up exactly with the Canadian totals shown above because of rounding errors)

COMMODITY-SPECIFIC RISK TO BIRDS	MIN	MAX	AVE	MIN	MAX	AVE

Saskatchewan	58.3%	39.4%	46.2%	58.3%	39.4%	46.2%
Alberta	20.2%	23.0%	20.4%	20.2%	23.0%	20.4%
British Columbia	2.2%	2.2%	2.5%	2.2%	2.2%	2.5%

Saskatchewan accounts for approximately half of the total estimated bird mortality, followed by Alberta and Manitoba. The prairies represent most of our area under crop and even if pesticide use in cereal or oilseed crops is less on a per hectare basis than in fruit and vegetable crops, to have this large of an area under crop means that a poorly chosen insecticide can have a major impact on birds.

In comparison, the cumulative number of cropped hectares over which avian mortality was likely, was a little over 6 million hectares in the U.S. (Mineau and Whiteside 2006). Using the range of kill rates documented above, this would mean an annual U.S. mortality of 3.16 to 14.6 million birds. This is a substantial reduction from just a few years earlier (1994-1998) when mortality was predicted on a little over 17 million ha. Using the same kill factors, the annual incidental take then would have been estimated at 8.88 to 41.0 million birds annually – approaching the 67 million estimated by Pimentel (1992). Because of restrictions imposed on the most toxic products, the number of 'hectares at lethal risk' has been dropping for most crops[7]. Again, these kill estimates are based solely on those species breeding in heavily agricultural landscapes and frequenting cropped fields – migrants are not included in this calculation. Also unaccounted are seed treatments, some of which could represent important sources of mortality as well as the few herbicides and most rodenticides which have the potential to kill birds.

Second approach

Based on a simplified field model and the incomplete list of pesticide sales information, the estimated incidental takes were compiled by active ingredient and presumed modal application rate (Table 8). Model results (in the form of predicted number of hectares sustaining mortality per province/territory) are given in appendix 2. The mortality estimates given here assume, as above, that when mortality occurs, there will be a loss of 0.52-2.4 adult individuals per ha.

Table 8. Predicted incidental take based on incomplete characterisation of insecticide sales data for Canada excluding Québec and Saskatchewan. Pesticides are ranked in decreasing order from most to least damaging to birds as measured by the estimated incidental take of adults.

Pesticide	Modal application rate (g a.i./ha)	Avian HD5 mg/kg bw	Predicted risk of mortality based on simple toxicity model	Estimated incidental take at low kill rate	Estimated incidental take at high kill rate
Chlorpyrifos	576	3.76	0.15	35054	161787
Diazinon	550	0.59	0.49	28909	133424
Carbofuran	528	0.21	0.71	14144	65279

---

[7] These restrictions were the result of U.S. legislation intended to better protect human health, especially children, and not in an effort to reduce avian mortality (Mineau 2006).

Permethrin	106	3127.00	0.00	0	0
TOTAL				**107069**	**494163**

These estimates are lower than those obtained using the first method, in part because of the incomplete and dated sales and use data available. Given that Saskatchewan accounted for approximately half of the total estimated mortality according to our first estimation method, the absence of any use data for that province is a clear problem. Estimates derived from this second approach therefore lack credibility. They are kept here because they do indicate which pesticides are likely causing the most mortality.

Associated loss of nesting opportunities

Incidental killing of adult birds by pesticides could take place at any point in the breeding season. Granular pesticides (or seed treatments not tallied here) would kill breeding individuals early in the season. Insecticide use is typically carried out at any point between seedling emergence up to a few weeks before harvest.

A very rough assessment of the number of lost nests is possible if we are willing to make a number of simplifying assumptions, viz.

1) Paired individuals from the same nest are likely to be killed together; there will be half the number of nests at risk than there are affected individuals;
2) Most agricultural species will have one re-nesting attempt;

3) An average success rate for most agricultural species will be one fledged young per nesting attempt;
4) Half of the kills will take place at the time when a nest is present and therefore result in the loss of the nest;

We can therefore easily envision the loss of 50% more individuals as a result of lost nesting opportunity. These assumptions are not very extreme and the additional breeding deficit is likely higher than this.

Discussion

Population relevance of the mortality

Many of the species most affected are well distributed farmland species. However, several of them (e.g. Horned lark, Vesper sparrow) are already in clear decline over most or all of their range. A link between pesticide use and regional population levels in the prairies has already been made (Mineau et al. 2005). Other forthcoming analyses (Mineau, unpublished) suggest that the direct acute and sub-acute toxicity of pesticides has significantly contributed to the decline of grassland/farmland bird species in North America.

The birds that are killed are ‘valuable members’ of the population. They have survived at least two full migrations, have returned to the breeding grounds and have successfully defended a territory. Therefore, any impact on this cohort is proportionately higher than similar estimates derived for other sources of mortality.

Mitigation

Mitigation of kills is relatively easy. Products that kill birds readily and reliably are well known and have been so identified. In most cases, substitution products of lower toxicity to birds already exist. Regulatory inaction is the only impediment to a reduction of the direct incidental take. Chronic and indirect effects will be slightly harder to mitigate although here also, much information exists on which products carry the highest risk.

Notes: The following crop combinations and substitutions were made in order to make the Census of Agriculture data to conform with USDA data from Mineau and Whiteside (2006).

- Barley includes mixed grain and buckwheat
- Beets includes rutabagas and turnip
- ‘Other berries’ assumed to be similar to blackberries
- Blueberries includes Saskatoon berries
- Cabbage includes Chinese cabbage
- Canola includes mustard seed
- Cherries includes both sweet and sour cherries
- Dry peas includes dry lentils and chick peas
- ‘Other vegetables’ assumed to be most similar to eggplant
- ‘Other field crops’ assumed to be similar to safflower
- ‘Seed crops’ includes forage seed, canary seed and caraway
- Squash included zucchini and mixed squash/pumpkin fields
- Wheat includes triticale

ABSTRACT

This study provides estimates for three sources related to power industry in Canada, which cause avian mortality: electrocutions, construction and transmission line maintenance, and water reservoirs. Estimates of avian mortality due to electrocution mortality for Canada (number of poles*birds/pole/year) ranged from 160,836 to 801,962 birds annually. Impacts are likely to be greater on raptors, owls, herons and cranes than on smaller, but more highly productive birds. Construction of transmission line likely impacted 2,588,494 nests and transmission line maintenance can possibly affect 388,274 nests each year. Avian mortality related to the construction and maintenance of transmission and distribution power lines is relatively small, and likely does not cause any significant impact at the population level. Operations of large water reservoirs created for hydro-power will rarely affect adults but result in the destruction of eggs in nidifigous species such as waterfowl and shorebirds or altricial species nestlings. An approximate estimate of avian mortality for Quebec due to hydro-power reservoirs gave us 152,162 nests/year, and does not cause a significant impact on a population level for any species. However, reservoirs within the breeding range of the Piping Plover (*Charadrius melodus)*, an endangered species, could affect the local population if highly estimated losses were recurrent every year.

INTRODUCTION

Power industry in Canada causes multiple impacts on bird species, due to electrocutions, construction and transmission line maintenance, establishment and operation of large reservoirs for hydro-power. This impact varies depending on species and habitat.

Electrocution

Electrocution mortality can have population level impacts in some areas on select species (Rubolini et al. 2001). The most publicized impacts occurred on large raptors such as Golden Eagle, *Aquila chrysaetos* (Boeker and Dikerson 1975, Benson 1981). While most of the literature about bird electrocutions focused on raptors, many non-raptors and migratory birds were listed as casualties, including waterfowl, herons, gulls, ravens and other passerines (Lasch et al. 2010, Janss 2000, Bevanger 1998, O'Neil 1988, Dexter 1953, Cartron et al. 2005, Manzano-Fischer 2006, Platt 2005, Anderson 1933). The extent of mortality on non-raptors is difficult to assess.

Recent reviews of available information worldwide concluded that reliable estimates of electrocution mortality are generally unavailable, several studies being affected by design and sampling issues (Lehman et al. 2007, 2010). Several factors contribute to electrocution risks (Roig-Soles and Navazo-Lopez 1997, Platt 2005, Lehman 2007) including bird morphology, age and sex (Ferrer et al. 1991, Dawson and Mannan 1995, Janss 2000, Harness and Wilson 2001), pole type, design and configuration (Boeker and Nikerson 1975, Orlendorff et al. 1981, Ferrer et al. 1991, Slater and Smith 2010) habitat and topography (Boeker and Nickerson 1975, Kochert and Orlendoff 1999), season and weather (Benson 1981, Janss and Ferrer 1999a, b, Harness and Wilson 2001, Platt 2005) which make global estimates of electrocution casualties difficult to collect.

Available estimates tend to be localised and biased by lack of information on detectability, and scavenging and crippling rates (Bevanger 1999). In the case of electrocution, detectability is not a major bias because birds tend to die close to the pole. However, scavenging and crippling rates estimates or lack of, can introduce important biases (Lehman et al. 2007). Reliable scavenging estimates are difficult to obtain as the use of surrogate species (i.e. chicken instead of eagles) can greatly bias estimates because small birds can be removed 10-20 time faster than larger birds (Smallwood 2007). Also, scavenging rates vary between seasons and sites (Bevanger 1995, Janss and Ferrer 1999a, b).

To date there is overwhelming evidence that most mortalities related to electrocution involve large birds mostly owls and raptors (Bevanger 1998, Lehman 2001, Platt 2005, Lehman et al. 2007, 2010, Manville II 2005). In Québec, confirmed bird electrocutions are mostly owls and raptors (Table 1). However, other species are electrocuted in larger numbers than raptors (Anderson 1933, Bevanger 1998, Dedon and Colson 1988, Janss and Ferrer 1999a, b, Janss 2000, Platt 2005, Tinto et al. 2010). Lasch et al. (2010) found that 56% of mortalities were corvids and gulls. Likewise Manzano-Fisher (2006) documented >50% birds that were electrocuted were ravens in her study. Platt (2005) in Alberta found 78% of electrocutions were non-raptors including ducks, gulls, sharp-tailed grouse, ravens, and other passerines. Janss (2000) found 33% of electrocutions were two species of migratory birds. Two old references provide insight into potentially overlooked causes of electrocution. Dexter (1953) found an electrocuted Northern Oriole (*Icterus galbula*) that appeared to have shorted out between a wire and a branch. Anderson (1933) recorded roosting Purple Martins (*Progne subis*) shorting out between wing tips resulting in group electrocutions.

Bird electrocution has been a continuous preoccupation for power line managers as it often causes power outage. In the United States, it is an important source of mortality for eagles (Harness and Wilson 2001). Several studies have looked at the efficiency of various measures to reduce casualties (Miller et al. 1975, Ledger 1984, Roig-Soles and Navazo-Lopez 1997, Janss and Ferrer 2001, APLIC 2006, Lammers and Collopy 2007, Slater and Smith 2010) but their efficiency is poorly documented (Lehman et al. 2007).

A detailed study in southeast Alberta (Platt 2005) in a 113,400 km^2 area yielded, after correcting for the effect of scavengers, losses of 542-2762 raptors, mostly Great Horned Owls (*Bubo virginianus*) and Red-tailed Hawks (*Buteo jamaicensis*) over a six week period spanning June-August. However, this study documented 61 non-raptor mortalities (page 30, Appendix D) compared to 33 raptor mortalities, or a ratio of nearly two to one. Thus the non-raptor losses would be about 1084-5524 birds in a 6 week period in the detailed study area which was only a small proportion of prairie Canada. This number may even be greater as removal experiments used large carcasses and likely underestimated removal rates of smaller birds. Because of the lack of standardized study in Canada, it is impossible to evaluate the number of migratory birds electrocuted each year. Because of their size and persistence, casual reporting of electrocution is likely biased towards large birds.

Construction and maintenance

Transmission line construction, maintenance, and creation of hydro-power reservoirs change a bird habitat during the breeding season, and therefore, may cause inadvertent nest destruction. In most cases it will rarely affect adults but will result in destruction of eggs in nidifugous species, and eggs or nestlings in atricial species. Sometimes, habitat modification and loss of nest may force adults to move to adjacent habitats and render them more vulnerable to predation.

The amount of casualties depends on nest abundance in habitat types destroyed during vegetation clearing for construction or during habitat vegetation maintenance activities. Casualties can be partitioned into two components: a) nests that would be destroyed during clearing of vegetation in construction phase, which is a one-time impact, b) nests that would be destroyed during maintenance activities, which is a recurring impact.

The main impact of reservoirs is the loss of habitats through inundation (Baxter and Claude 1980). However, fluctuating water levels associated with reservoir exploitation may also flood nests (Wolf 1955, Books 1985). Nest mortality here is partitioned into three components: a) nests that would be destroyed during clearing of vegetation prior to initial flooding; b) nests that would be flooded during reservoir filling; c) nests that would be flooded during annual water fluctuations related to reservoir exploitation. The first two are one time effects whereas the third one is a recurring effect leading to cumulative impacts.

To our knowledge, few adequate studies of bird mortality due to power lines have been done in Canada (Platt 2005) to generate credible estimates for each province. Here, we coarsely estimate losses due to electrocution, construction and maintenance of transmission and distribution power lines, and grossly estimate IT due to creation and operation of large water hydro-power reservoirs in Canada.

METHODS

Electrocutions

As expected, estimates of bird electrocution rates varied wildly between 11 studies compiled (Table 2). When estimates are expressed in number of birds/pole/year, we often obtain minimum and maximum values depending on the study (Table 2). Minimum values are based on confirmed cases of electrocution only whereas maximum values include all birds found (It is often difficult to determine the exact cause of mortality). We derived average values using: 1) the smaller of two values when two estimates were provided and 2) the maximum value. This yielded average estimates of 0.0281 and 0.1401 bird/pole/year respectively (Table 2). However, results from the Alberta study are based on a relatively short period and contrast with other values. If we exclude values from this study, we obtain average estimates of 0.0066 and 0.0797 bird/pole/year (min and max; Table 2). Estimates are usually per year although this is not clearly stated in some studies. The coefficient of variation was quite high (minimum estimate = 172%; maximum = 132%) indicating the wide range in estimates. If we exclude the Alberta study, the coefficient of variation drops to 52-97%. Given differences between minimum and maximum average estimates we derived estimates for both. Also, because of the unique high estimates obtained in the Alberta study compared to other studies, we derived estimates excluding that study.

Transmission line maintenance and construction

To derive an estimate of casualties in terms of number of nests destroyed during construction or maintenance, we multiply area cleared during the breeding season by nest density at the time of vegetation clearing.

Landbird density estimates

DesGranges et al. (2003) compiled and derived breeding bird estimates in diverse types of forested habitats in Quebec (Table A1.1). Estimates of breeding densities ranged between 2.73 and 4.64 pairs/ha and averaged 3.78 pairs/ha. One forest type left out of this average is jack pine which averaged 0.82 pairs/ha. Another source of breeding bird density data is the Bird Census database (Kennedy et al. 1999) which covers several areas of Canada. Estimates of breeding densities varied between locations and habitat types from 0.33 birds/ha in young Englemann spruce/subalpine fir to 11.9 birds/ ha in mid-age bur oak/green ash/Manitoba maple. Estimates for regenerating clearcuts, a typical habitat found under managed power lines, averaged 8.02 birds/ha (n = 18 plots) or 4.01 pairs/ha (Table A1.2; Kennedy et al. 1999).

Yahner et al. (2004) reported breeding densities of 11.4, 5.0 and 3.8 pairs/ha in right of way corridors. Bramble et al. (1994) reported densities of 9.63 to 15.81 pairs/ha for differently managed right of way corridors. Thus there could be large fluctuations in breeding bird densities depending on location, habitat types and years. Breeding bird densities varied between BCR zones from 3.70 pairs/ha in the Northwestern Interior Forest Zone to 7.74/ha in the Northern Pacific Rainforest Zone (Hobson 2011). However, Savard et al. (2000) reported estimates based on spot-mapping results for the coastal forests of British Columbia ranging between 1.25 and 4.64 pairs/ha depending on forest type and age (Table A1.3).

The above density values represent total breeding density estimates and assume that all species breed simultaneously which is not the case. At any one time, it assumes that all species would have nests at the time of vegetation clearing which is not realistic as the breeding season extends from early may for resident species to late June-early July for neotropical migrants, and several species do re-nest when their nests are destroyed early in the season. Also, a small proportion of nests would have already failed at the time of habitat modifications.

Clearing of a given area will likely take only a few days and the number of active nests will vary according to the timing of the clearing. Also, breeding bird densities and predation pressures can vary greatly between years in relation to weather, insect epidemics and other resources abundance. Because of the difficulties of quantifying these factors and their great yearly variability, for the purpose of this exercise, we assume that 30% of the nests were active in May, 90% in June and 30% in July. These proportions vary between areas (north vs south) and years depending on climate conditions. Therefore, we also generate estimates assuming that 100% of the nests were active each month.

Transmission lines length

In Quebec, it is estimated that there are about 12,216 km of transmission lines (Tecsul 2009) and 219,750 km in the rest of Canada (Canadian Electricity Association). However, according to Hydro Quebec web site, the number calculated by Tecsul (2009) may not cover the whole province as it is reported that there is 32,000 km of transmission lines in Quebec. The latter figure will be used in this report yielding a total of 251,750 km of transmission lines in Canada (32,000 km in Quebec and 219,750 km in the rest of Canada). The total length of distribution lines in Canada is 572,370 km.

Reservoirs

Area covered by reservoirs

Approximately 14,831km^2 were inundated by the creation of reservoirs in northern Quebec, within the boreal forest Bird Conservation Area (BCR 8; Table A2.1). These estimates represent the total area of the current reservoirs but naturally occurring water bodies were already covering a portion of the landscape prior to the creation of the reservoirs. For example Tecsul (2009) estimated the area actually flooded in BCR 8 at 4,112 ha, nearly 3 times less than the total area covered (Table A2.2). For the rest of the current exercise, we will use the data from Table A2.2 (Tecsul 2009).

Waterfowl breeding densities

Waterfowl densities vary temporally and spatially throughout the various Canadian ecosystems. Savard and Lamothe (1991) summarise values for northern Quebec and Labrador for scoters (Surf and American Scoters, *Melanitta perspicillata and M. americana*) with a maximum value of 18 pairs/100km^2 (0.18/km^2). Transect results yielded an estimate of 0.514 pairs/km^2 for the entire waterfowl community. Lemelin et al. (2004) report densities ranging from 0.89 to 1.33 pairs/ km^2 in the forested areas south of 51°0 15’ N, and Bordage et al. (2002) report a density of 0.86 pairs/km^2 in the area of the Gouin reservoir. None of these estimates have been corrected for detectability biases so they should be considered as minimums. Recent surveys in Labrador yielded waterfowl densities in 25m^2 plots ranging from 0 to 4.14 pairs/ km^2 (Table A1.4; Gilliland et al. 2008, 2009). The maximum estimate of 1.33 pairs/km^2 (Lemelin et al. 2004) was used to derive casualties related to flooding of northern reservoirs. The estimate is similar to the mean obtained in Labrador in 2009 (Table A1.4; Gilliland et al. 2009).

Waterfowl species composition

The abundance and diversity of breeding waterfowl varies throughout the boreal forest depending on location and scale considered (Tables 4 and 5). In the areas affected by northern reservoirs in Quebec, the most numerous waterfowl species average 8.4 eggs/ nest and approximately 8.0 eggs/nest in the area of the reservoir Gouin (Table A1.5). None of the species involved are considered of concern in Canada.

RESULTS

Electrocutions

To derive reliable estimates in relation to casualties in Canada due to electrocution, we used data from the literature on the numbers of bird killed/pole/year (Table 2) and applied it to Canada. The total length of distribution lines is estimated at 572 370 km. If we assume about 10 poles/km, we obtain a total of 5 723 700 poles. Estimates of avian mortality (poles * birds/pole/year) ranged from 160 836 (min) to 801 962 birds annually. If we exclude the Alberta study, estimates drop to 37 490 and 456 261 birds per year. Based on the Alberta study (Platt 2005; Table 3), only about 10% of the birds electrocuted are migratory, whereas the rest are species under provincial jurisdiction. It gives us an estimate from 16 084 to 80 196 migratory birds electrocuted annually in Canada.

Transmission and distribution line construction and maintenance

We averaged the breeding bird density of each data source found in Tables 1-3 (3.78; 4.48; 3.38). This yielded an average of 3.88 ± 0.56 pairs/ha (SD; CV = 14.4%). If we take the maximum from each data base (7.76, DesGranges et al. 2003; 11.9, Kennedy et al. 1999; 6.98, Savard et al. 2000) we obtain an average estimate of 8.88 ± 2.64 (SD; CV = 29.7%).

Assuming a width of about 100m (0.1km) we derive an area of 25,175 km² or 2,517,500 ha of habitats cleared for transmission lines. In the estimates below, we assume that only half of the area was cleared during the breeding season in the following pattern: 10% in May; 40% in June; and 50% in July. We also assume that 20% of nests are active on any given day in May; 90% in June; and 30% in July. Based on these assumptions, we derive two estimates, one based on average values (3.88 pairs/ha) and one based on maximum values (8.88 pairs/ha).

Those yielded respectively casualties of 2,588,494 and 5,924,181 nests related to the construction of transmission lines in Canada. If we change the proportion of nests active in May from 20% to 50%, in June from 90% to 90% and in July from 30 to 50% we obtain casualties of 3,223,407 and 7,377,282 nests respectively. Also, changing the proportion of clearing done in May, June and July affects estimates only slightly but changing the average breeding bird density has the most impacts (Fig. 1). I should point out that those are cumulative estimates as the construction of transmission lines in Canada was spread over several decades so that the yearly impact was much smaller in any given area.

To derive casualty estimates for maintenance, we assumed that the impact was similar to the one related to the construction phase and occurred only every 5 years or 10 years. Estimates were generated for both scenarios. Assuming a five years recurring management results in estimates that are one fifth of those previously derived (min = 517,699 nests/year, max = 1,184,836 nests/year); if maintenance was only done every 10 years which may be the case in the boreal forest where vegetation growth is slower, casualty estimates are half again (min = 258,849, max = 592,418).

Final casualty estimates based on the authors' unsupported assumptions (educated guess) are: 1) use of average breeding bird density estimates as best representing the variability in habitat types and yearly fluctuations; 2) use of a 5 years recurring maintenance schedule for 60% of the lines, of 10 years for 30% and of 0 maintenance for 10%. This scenario yield initial casualties related to construction of 2,588,494 nests and recurring nest mortalities of: 0.60 * 517,699 nests/year + 0.30 * 258,849 = 388,274 nests/year.

Estimated avian mortality in relation to hydro-electric reservoirs

Hydro-electric reservoirs in Quebec

Approximately 8,342 km^2 were inundated by the creation of reservoirs in northern Quebec over the last 40 years (Table A2.2). This yields an estimate of 11 095 nests (8,342 km^2 X 1.33 pairs/km^2) potentially affected if these reservoirs were all filled during the breeding season. However, this is not the case as most large reservoirs take two to three years to fill up covering multiple breeding seasons but affecting different areas. As the breeding season is fairly short in the boreal forest we assumed that waterfowl nests are only vulnerable for a period of two months each year.

Assuming a constant rate of reservoir filling throughout the year over a two year horizon, nests would be vulnerable for four of 24 months (16.6%). This assumption is questionable as reservoir filling may take more than two years, the area flooded depends on slope and filling would be quicker during spring runoff than at any other time of the year and will depend also on precipitation levels. However, each reservoir situation is different so that it is difficult to determine adequate assumptions. If we apply this percentage (16.6%) to the 8,342 km^2 flooded area, 1,385 km^2 would have been affected during the breeding season. This translates into 1,842 waterfowl nests that could have been affected.

Assuming an average clutch size of 8.4 eggs (Table A2.2; weighted average), it represents 15,473 eggs lost in relation to the filling of the reservoirs. This would have been a one-time impact.

Other reservoirs in Quebec

Lehoux et al. (1991) conducted a study of the impact of fluctuating water levels in the Montreal/lac Saint-Pierre sector of the St. Lawrence River. These fluctuations were not directly related to hydro-electricity but were mostly for navigation considerations. However, because of the high productivity of the impacted areas, it affects productive waterfowl habitats and results in casualties. Impacts varied yearly with the level of water fluctuation and its timing (Fig. 2). Waterfowl breeding densities in the freshwater portion affected by water level controls were evaluated at 23 nests/km^2 (0.23 nest/ha), densities very high compared to northern forested habitats. As expected, the highest impacts occur with the highest water levels and the number of nests potentially impacted varies with the timing in regard to nesting chronology (Fig. 2). It should be noted that increase in water levels before or after the breeding season will not result in casualties. Unlike reservoirs for which the major impact was at the time of filling, in the case of the St. Lawrence, it occurs at various levels every year and with various timing, making it difficult to generate credible estimates.

British Columbia

A detailed study of avian nest mortality in relation to water level fluctuations in reservoirs was made for the Kinbasket and Arrow Lakes reservoirs in the Columbia valley of British Columbia (BC Hydro unpublished data). Most nest failures were due to predation (78.3%, n = 258 nests, in the Arrow Lakes Reservoir and 77%, n = 352 nests, in the Kinbasket Reservoir). The failure of seven nests (5.8%) was directly caused by reservoir operations, all in the Arrow Lakes Reservoir. No nest losses could be attributed to reservoir operations in the Kinbasket Reservoir. Clearly, in this study at least, avian mortality was low. However a study of the drawdown zones of the Columbia River reservoir network documented several nest flooded by rising water levels but concluded that impacts were negligible from a population perspective but could be significant locally when locally rare species are affected (BC Hydro unpublished data).

Other potential losses of non-waterfowl species due to reservoir flooding

Activities related to the initial creation of reservoirs may cause some avian mortality when the habitat is modified prior to flooding. However, the area affected cannot be adequately measured as habitat modification does not occur in all reservoirs (in some, trees are cut prior to flooding, in others not). Also, there is no easily available information as to the period when the clearing was done. Assuming that 75% of the reservoir area in northern Quebec was cleared (6,257 km^2 or 625,700 ha) and that half of the clearing was done during the breeding season (3,129 km^2 or 312,850 ha) we obtain, assuming that all the area cleared was forested and sustained a density of breeding birds of 37.8 pairs/10ha (3.78/ha; Table A1.5), an estimate of 1 182 573 nests affected. This is very likely a maximum estimate as breeding bird densities in these areas are likely lower and that a mixture of habitats were affected. Hobson (2011) calculated that the proportion of forest harvesting occurring during the breeding season in Canada ranged from a low of 12% and a high 26%. Application of these percentages here yield casualties of 280,063 nests (75,084 ha * 3.73 nest/ha) and 606, 804 nests (162,682 * 3.73nest/ha), respectively.

In the worst case scenario, water levels would rise quickly to the 7.98 meter at Sorel in early to mid-June. Such a scenario could impact 600 nests which, with an average clutch size of 8 eggs would represent 4800 eggs. Clearly, such a scenario would significantly impact the productivity of the local waterfowl population estimated at about 900 nests.

Impacts at the population level

Indeed the worst case scenario in Northern Quebec, the province with the greatest number of reservoirs in terms of area, resulted in less than 1842 nests affected total and, this distributed across several species. The impact of such losses at the population level will have to consider natural mortality at both the nest and brood stages. As mortality factors vary greatly from year to year, the impact on the local population will also vary accordingly. Assuming a survival of 50% of nests and a 50% survival of broods reduce the impact to a loss of 461 waterfowl nests and of (using Hobson 2011 estimate of 26 % harvest during the breeding season) 151,701 non waterfowl nests . Thus, once natural mortality is considered, a total of 152,162 nests were lost due directly to reservoir flooding.

DISCUSSION

Summarizing calculations from multiple sources analyzed above, we obtain the combined estimates of casualties caused by power lines ranging from 160,836 to 801,962 adult birds and 388,274 nests in Canada, annually. Due to lack of data, we cannot provide a reliable estimate of casualties caused by hydro-power reservoirs for Canada, but Quebec, the province with the greatest number of reservoirs in terms of area gives us 152,162 nests affected.

Electrocution

Electrocutions are mostly associated with distribution lines and are relatively uncommon on transmission lines, which is the reverse for collision casualties. Clearly better data are needed, especially for poles in the boreal forest which may not cause excessive mortality because of habitat structure, species composition and behaviour of raptors there. We also need more accurate data for open areas, i.e. prairies with greater raptor densities, where poles provide an attractive structure for hunting and resting birds. The abundance and types of poles in Canada need to be quantified better, as electrocution risks are directly related to pole types. Their spatial occurrence has to be evaluated as risks vary greatly for a given type of pole depending on the surrounding habitat.

Due to relatively small amount of migratory birds reported electrocuted (most are raptors and owls), mortality of migratory birds due to electrocution cannot be properly evaluated. Thus impacts at the population level are hard to assess. Impacts are likely to be greater for the long-lived species, such as raptors, owls, herons, and cranes than on smaller, short-lived, but highly productive birds. In some cases, local populations of some owls and raptors could be significantly affected (Sergio et al. 2004). Newly developed strategies to identify problematic poles have been focused on modeling to identify problematic pole types (Manosa 2001, Tinto et al. 2010) but this approach has still to be applied in Canada. Electrocution of birds has not been recognised as a national issue in Canada, in part because of the focus of the literature on large raptors and lack of studies.

Construction and maintenance

To derive accurate estimates of avian mortality related to the construction of transmission lines, we need an estimate of the length of diverse habitats traversed by these lines throughout Canada as well as estimates of breeding bird densities within these habitats. It also requires an estimate of the period of the year when vegetation was cleared, which is not currently available.

On transmission system lines, the wires are not insulated by a sheath and air acts as the insulator. When vegetation comes close to the conductors (wires), there is a risk of an electrical arc forming which may cause a power outage, start a fire and even electrocute people in the vicinity. To avoid this occurrence, vegetation under transmission lines has to be kept relatively short and thus need to be managed on a regular basis.

For Hydro-Québec, the vegetation management period begins after snow melting in spring and continues into the fall. Vegetation control under transmission lines is done about every five years, depending on the climate zone and the method used. The farther north a line is located, the less frequent the clearing operations, since vegetation at higher latitudes tends to grow at a slower rate.

Hydro-Québec uses three methods for clearing rights-of-way, either alone or in combination: a) selective cutting (using chainsaws, brush cutters and mowers); b) selective application of herbicides (pesticides that kill certain plants or inhibit their growth, while allowing other plants to develop); c) land-use development (bicycle paths, crop cultivation, gardens, etc.). The last one creates habitats not suitable for breeding. In general, Hydro-Québec uses only mechanical cutting to control vegetation in rights-of-way in 70% of all cases. The other work consists of a combination of mechanical cutting and selective application of herbicides. As the proportion of lines managed by each method is unknown and given that the use of herbicide is often preceded by vegetation clearing, it will be assumed here that all methods result in similar impact. The maintenance of distribution lines may result in some nest mortalty but it is done differently and involves mostly branch trimming rather than whole tree removal.

Reservoirs

Losses associated with creation of hydro-electric reservoirs at the population level are not significant locally, globally, and at the species level, for most if not all species of waterfowl, considering the populations of several millions. However, we have to take into account that losses are calculated for Quebec only and do not include other provinces. More factual data on each reservoir in each province are needed to obtain refined estimates.

This exercise, although highly speculative, suggests that avian mortality related to reservoir flooding is negligible at provincial scale, and it is unlikely to cause significant impact for any species. One cautionary note: reservoirs within the breeding range of the Piping Plover (*Charadrius melodus)*, an endangered species could be used for nesting by the species, rendering nests susceptible to flooding and could affect the local population if such losses were recurrent every year.

There is no impact related to vegetation removal if it is done outside of the breeding season. Often, prior to reservoir flooding, trees are cut to reduce boating hazards and limit the vegetation decomposition, which affects water chemistry. However, within the breeding season the impact will be similar to that of forest harvesting (in forested areas) and mostly limited to the destruction of eggs and/or nestlings, whereas adults remain unaffected. Therefore, nest mortality is proportional to the number of active nests in the harvested area.

Similarly, no impact related to flooding occurs outside the breeding season. If done during the breeding season, it will affect mostly ground nesting species in the flooded area. In some cases, especially when shrubs are abundant, it will harm shrub nesting species and could even take species breeding in small trees.

Most artificial reservoirs have fluctuating water levels in relation to precipitation and water usage. These levels often do not coincide with natural water fluctuations and could flood nests built in the affected zone (Nilsson and Dynesius 1994, Lehoux et al. 2003). In most large reservoirs (km^2), especially those with unnatural and important fluctuations (a few meters), little vegetation is established in the affected zone, and nesting is minimal. However, in the north of Canada, and also possibly in the prairies, this bare zone attracts some species of ground nesting shorebirds. In those cases, primarily eggs are impacted as the nidifugous young can avoid flooding (they may perish indirectly due to lack of habitat and greater susceptibility to predation). However, the impact is limited to the breeding season, mostly eggs and nestlings, and it is local. In the special case of the Great Lakes-St. Lawrence system where water levels are controlled for navigation, unnatural water fluctuations occur often and have potential of flooding waterfowl, terns and other ground nesting waterfowl nests (Lehoux et al. 1991).

Unfortunately, reliable estimates for the area flooded by reservoirs in most of the other provinces could not be obtained. However, it is much smaller than the area in Quebec, and in general most reservoirs in other provinces are smaller. There might be localised losses due to fluctuations in water levels each year but this is very likely insignificant as for most reservoirs, the marnage zone is often devoid of vegetation and not very attractive for ground nesting birds. Besides, to cause an impact, the water rise would have to coincide with the nesting period. Furthermore, the area affected by flooding due to yearly water fluctuations is much smaller than the area initially flooded. However, if flooding occurs each year at the time birds have already initiated their breeding activities, it would result in recurring yearly losses. These conditions vary from reservoir to reservoir, and they require local data to estimate losses.

CONCLUSIONS

Given IT numbers for electrocutions unlikely result in significant population effect on individual species with possibly some exception for some endangered species such as Whooping Cranes (*Grus americana*). Nest mortality related to the construction and maintenance of transmission and distribution power lines was grossly estimated but seems relatively small, and would not cause any significant impact at the population level. Nest mortality caused by hydro-power reservoirs is considered negligible, however, it is highly speculative, in great part because of the coarseness of the data available on reservoirs size, the way they were filled, and the yearly water fluctuations and timing. Data on breeding bird densities could also be refined. Finally, detailed studies similar to those in British Columbia (BC Hydro unpublished data) or to Lehoux et al. (2003) in the St. Lawrence are greatly needed to derive more realistic and credible estimates for each reservoir.

ACKNOWLEGEMENTS

We would like to thank Geoff Holroyd for his pertinent comments and suggestions, and Dr. Robert Elner for his insightful comments.

[†] The study was done over a 6 weeks period in June and July. To derive annual estimates we extrapolated to 6 months or 20 weeks (May to October included). Rates: 64 birds for 379 poles during 6 weeks = 0.1689 birds/pole/6 weeks; this yield an estimate of 0.5629 birds/pole/20 weeks. We assumed no death from November to late April. Only 13 birds were confirmed as electrocuted; this yields a minimum estimate of 0.1143 birds/pole/20 weeks.

[‡] Excluding the Alberta study.

Table 3. Number of individuals recovered during a 6 weeks period (June and July) in Alberta during two searches of 379 poles (Only 13 of the birds recovered could be confirmed as being electrocuted). Scavenging efficiency was estimated at 62% over this period.

[‡] Number of nests affected

Table 5. Relative abundance of ground nesting waterfowl in northern Quebec in the area of important Hydro-electric reservoirs (Savard and Lamothe 1991).

Species	Young counted, %	Clutch size
Merganser (*Mergus* sp)	30.9	11
Canada Goose (*Branta canadensis*)	20.5	5
Black Scoter (*Melanitta. americana*)	19.8	8
Surf Scoter (*M. perspicillata*)	13.2	8
Scaups (*Aythya sp.*)	7.2	9
Scoter (*Melanita* sp.)	3.0	8
American Black Duck (*Anas rubripes*)	2.4	12
Common Loon (*Gavia immer*)	1.3	2
Mallard *(A. platyrhyncos*)	0.8	10
White-winged Scoter (*Melanitta deglandi*)	0.5	8
Red-throated Loon (*Gavia stellata*)	0.4	2
Mean		9.5
SD		1.5
CV (%)		16

Table 6. Relative abundance of waterfowl (% of pairs observed) in northern Quebec near the Hydro-electric reservoir Gouin (Bordage et al. 2002).

Species	% pairs	Clutch size
American Black Duck (*A. rubripes*)	30.6	12
Common Merganser (*Mergus merganser*)	22.1	12
Common Goldeneye (*Bucephala clangula*)	18.8	-
Ring-necked Duck (*Aythya collaris*)	11.3	9
Common Loon (*Gavia immer*)	6.7	2
Canada Goose (*Branta canadensis*)	5.1	5
Mallard (*A. platyrhyncos*)	1.7	12
Green-winged Teal (*Annas crecca*)	1.4	10
Bufflehead (*Bucephala albeola*)	1.3	10
Hooded Merganser (*Lophodytes cucullatus)*	0.9	11
Mean		9.2
SD		3.5
CV (%)		38

APPENDIX 1. Breeding bird density estimates from the literature.

Table 1. Breeding birds densities (pairs/ha) in major forest types in Quebec (DesGranges et al. 2003).

Forest type	Mean	SD	SE	n	CV
Maple	4.64	1.14	0.57	4	25
Aspen	3.90	1.51	0.87	3	39
Balsam-fir	4.09	0.92	0.41	5	22
Birch	3.50	0.83	0.48	3	24
Sruce	2.73	0.90	0.37	6	33
Poplar	4.06	-	-	1	0
Larch	3.76	0.65	0.46	2	17
Pine	3.53	0.21	0.12	3	6
Average	**3.78**	**0.56**	**0.20**	**8**	**15**

Table 2. Breeding birds densities (Pairs/ha) in major forest types in Quebec (Kennedy et al. 1999).

Primary habitats	Low	High
Broad-leafed forest/woodland	1.70	5.95
Conifer and mixed forest/woodland	0.17	4.60
Wetlands	0.73	5.09
Open land	0.22	3.51
Urban area	2.00	3.25
Average	**0.96**	**4.48**
(SD)	**(0.85)**	**(1.12)**
(SE)	**(0.35)**	**(0.46)**

Table 3. Breeding bird densities (Pairs/ha) in coastal forests of British Columbia (Savard et al. 2000).

Location	Forest type	Mean	SE	n	Range
Queen Charlotte Islands	Old growth	4.64	0.67	3	3.32-5.17
	40-80 years old	3.17	0.06	3	3.12-3.29
	Clearcuts	1.25	0.24	2	1.09-1.42
Vancouver island	Old growth	3.27	0.05	3	3.17-3.34
	40-80 years old	2.64	0.12	3	2.41-2.77
Mainland South Coast	Old growth	4.38	0.92	4	2.98-6.98
	40-80 years old	3.29	0.30	4	2.46-3.82
	Deciduous stands	3.91	0.70	3	2.72-5.14
	Clearcuts	3.85	0.34	2	3.61-4.09
Average		**3.38**	**0.34**	**9**	**1.25-4.64**

Table 4. Breeding densities (pair/km^2) of waterfowl in Labrador.

	Mean	Range	n
1998	1.15	0.08 - 3.92	31
1999	1.45	0.00 - 4.14	31

APPENDIX 2. Area covered[†] by hydroelectric reservoirs.

Table 1. Area covered[†] by hydroelectric reservoirs in northern Quebec, BCR 8 (Wikipedia, September 2010).

Reservoir	Area (km^2)
Gouin	1570
Dozouais	319
Manicouagan	1942
Caniapiscau	4318
Eastmain	6682
Total	14,831

[†] this likely represent the area currently covered by reservoirs which is greater than the actual flooded areas.

Table 2. Area covered by hydroelectric reservoirs in the different BCR in Quebec (Tecsul 2009).

Bird conservation region	Area (km^2)
14	91
13	292
12	3665
8	4112
7	91
3	91
Total	8342

Appendix 2 – Details of parameter values and distributions used in stochastic model of anthropogenic avian mortality in Canada.

Table A2.1 – Distributions used to describe species-group composition, age-group breakdown and seasonal distribution of anthropogenic avian mortality for each source, used in the stochastic model to convert stage-specific losses to a total loss of potential adult breeders. When all characteristics were known, no distributions were necessary (e.g. agricultural mortality was entirely measured in loss of eggs of landbirds, and therefore there was no uncertainty in species-, age- or seasonal-breakdown).

Appendix 3. Details of population-level impacts of anthropogenic avian mortality in Canada.

Table A3.1 –Total mortality relative to abundance for species (or regional populations) and families, as illustrated in Fig. 2. Original stage-specific mortality totals presented in each paper are listed by life stage (*Ke*: eggs/nestlings, *K-unk.*: unknown-age mobile individuals; *Kf*: fledglings; *Ka*: adults), as well as the total converted mortality in equivalent number of adult breeders is also shown (*M*). The proportion value in the final column (%) represents the ratio between M and abundance. Abundance estimates are those provided directly by authors, except for building collisions, where family-level abundance was derived from current Canadian estimates (Blancher 2002, P. Blancher *unpubl. data*), and used to estimate proportional kill (M / abundance).

Source	**Species or family (region)**		**Group**	***Ke***	***K-unk.***	***Kf***	***Ka***	***M***	**Abundance**	**%**
Marine bycatch	Common Murre (Funk Is.)	*Uria aalge*	Seabirds	-	-	-	4,500	4,500	984,000	**0.46%**
Marine bycatch	Black-footed Albatross	*Phoebastria nigripes*	Seabirds	-	-	-	99	99	2,500	**3.96%**
Marine bycatch	Common Eider (SW NS)	*Somateria mollissima*	Seabirds	-	-	-	532	532	7,600	**7.00%**
Marine bycatch	Northern Gannet	*Morus bassanus*	Seabirds	-	-	-	320	320	160,000	**0.20%**
Marine bycatch	Great Shearwater	*Puffinus gravis*	Seabirds	-	-	-	2,346	2,135	1,500,000	**0.14%**
Oil and gas - marine	Leach's Storm-Petrel	*Oceanodroma leucorhoa*	Seabirds	-	-	62	-	12	20,000,000	**0.00%**
Oil and gas - marine	Thick-billed Murre	*Uria lomvia*	Seabirds	-	126	-	-	71	8,000,000	**0.00%**
Oil and gas - marine	Common Murre	*Uria aalge*	Seabirds	-	32	-	-	18	2,000,000	**0.00%**
Oil and gas - marine	Dovekie	*Alle alle*	Seabirds	-	2,086	-	-	1,157	132,000,000	**0.00%**
Oil and gas - terrestrial	Sprague's Pipit	*Anthus spragueii*	Landbirds	-	-	-	482	482	613,000	**0.08%**
Oil and gas - terrestrial	Western Meadowlark	*Sturnella neglecta*	Landbirds	-	-	-	550	550	2,100,000	**0.03%**
Oil and gas - terrestrial	Canada Warbler	*Cardellina canadensis*	Landbirds	-	-	-	74	74	210,000	**0.04%**
Oil and gas - terrestrial	Ovenbird	*Seiurus aurocapilla*	Landbirds	-	-	-	730	730	1,750,000	**0.04%**
Wind energy	Horned Lark	*Eremophilia alpestris*	Landbirds	-	1,480	-	-	1,171	30,000,000	**0.00%**

Wind energy	Golden-crowned Kinglet	*Regulus satrapa*	Landbirds	-	888	-	-	702	23,000,000	**0.00%**
Wind energy	Red-eyed Vireo	*Vireo olivaceus*	Landbirds	-	888	-	-	702	96,000,000	**0.00%**
Wind energy	European Starling	*Sturnus vulgaris*	Landbirds	-	740	-	-	585	30,000,000	**0.00%**
Wind energy	Tree Swallow	*Tachycineta bicolor*	Landbirds	-	592	-	-	468	12,000,000	**0.00%**
Wind energy	Canada Warbler	*Cardellina canadensis*	Landbirds	-	44	-	-	35	1,350,000	**0.00%**
Wind energy	Chimney Swift	*Chaetura pelagica*	Landbirds	-	44	-	-	35	145,000	**0.02%**
Agriculture (haying)	Bobolink	*Dolichonyx oryzivorus*	Landbirds	666,784	-	-	-	48,570	3,991,300	**1.22%**
Agriculture (haying)	Savannah Sparrow	*Passerculus sandwichensis*	Landbirds	940,697	-	-	-	68,522	23,628,000	**0.29%**

Appendix 4. Methodology for maps of anthropogenic avian mortality risk.

Overview

The two maps shown in main manuscript were created by assembling vector format data layers and overlaying a 50 × 50 km tile grid for summarizing the data. We calculated the relative proportion of each source of mortality occurring in each grid square as a function of direct or indirect measures of intensity of each mortality source. The estimated kill for each source was then allocated across the applicable grid tile according to the proportional intensity of the mortality source calculated. The tile grid was used to summarize the overall bird mortalities occurring across Canada based on the following seven data layers representing eight sources of terrestrial mortality:

- Roads
- Communication Towers
- Terrestrial Oil and Gas
- Forestry
- Agriculture
- Population Density (used as an index of building and cat distribution)
- Wind Farms.

These were the only sources for which suitable data were available for mapping. A detailed summary of data sources, manipulations, and a map for each mortality source is provided in this appendix. All work was done in ArcGIS 10.0 and area calculations were done in Albers Equal Area Conic projection. Specific procedures/functions are noted to encourage replication or improvement.
